New facilities to advance understanding of radiation damage in REBCO superconductor

Zach Hartwig, Alexis Devitre, David Fischer, Zoe Fisher, and Dennis Whyte

MIT Plasma Science and Fusion Center (PSFC)

Presentation to the First Muon Collider Collaboration @ CERN

Eni S.p.A has generously supported all work in REBCO irradiation shown in this presentation
MIT PSFC is pursuing broad R&D in high-field REBCO magnets

- Insulated cables (>50 kA)
- No insulation coils (>30 T)
- The SPARC Toroidal Field Model Coil (large-scale 20 T 110 MJ coil)
- Non-planar 3D cables and coils
- High-fidelity radiation damage in REBCO
- 50 kA LN2-cooled binary current leads
- Defect tolerant cables and magnets

MIT PSFC is interested in collaborating on high-field REBCO technologies
Radiation damage in REBCO magnets is a key technical, operational, and economic challenge for fusion devices.

Despite shielding, fast neutrons reach REBCO in the toroidal field coils of a tokamak fusion power plant. (note: while magnets operate @ 20K)

Toroidal Field (TF) magnets in a fusion tokamak power plant are a significant fraction of capital cost and are expected to be lifetime components.

Quantifying limits due to radiation damage in high-field REBCO magnets will be necessary to:
• Optimize complex system design of tokamak core
• Anticipate operational concerns (e.g. thermal annealing, magnet stability changes, etc.) and understanding plant availability (key cost driver)
• Forecast capital cost of fusion power plants and ultimately economic viability as an energy tech.

What have we done in this area and, more importantly, what new capabilities based on what we’ve learned so far can we deploy to advance our knowledge?
The TFMC was built on no-insulation REBCO magnet technology; Perhaps removing insulation is a first-step in radiation tolerance?

The TFMC winding pack, with no turn-to-turn insulation nor high-voltage to drive breakdown should pancake-to-pancake insulation degradation occur...

</table>

Aside: ~20 K operation with single pass helium cooling via pressure vessel provides very high heat removal capabilities with intrinsic cryostability
Radiation damage in REBCO has been advanced through reactor neutron irradiations and, more recently, proton irradiation.

- Neutron irradiations @ 330 K followed by cryogenic, high-field $I_c(B,T)$ characterization
- Clear temperature dependence indicates pinning force changes via defect size vs. vortex scale length
- Degradation limits determined to be $\sim 5 \times 10^{22} \text{ n/m}^2$

- Proton irradiations @ 80 K followed by cryogenic, mid-field $I_c(B,T,\theta)$ characterization
- Radiation damage destroys “advanced pinning” advantage for $B \parallel ab$ but enhances off-axis $I_c$
- Irradiation temperatures make a critical difference

MIT has been pursuing increasingly high-fidelity capabilities to properly understand radiation damage in REBCO tapes

- The vast majority of radiation damage in REBCO has been studied in conditions that are not representative of an operating SC magnet. Examples:
  - Elevated irradiation temperature (>330 K vs ~20K)
  - Poorly matched neutron energy spectra
  - Thermal annealing between damage and $I_c(B,T,A)$

- Why?
  - Lack of cryogenic neutron irradiation capability worldwide (Russian, German, Japanese, US reactors shuttered)
  - Difficult to match D-T 14.1 MeV fusion neutron spectra (especially at relevant $\sim 3 \times 10^{22}$ n/cm$^2$ fluences)
  - Challenging to perform in-situ irradiation and $I_c(B,T,A)$ measurements (particularly in test reactors)

One method of attack is through materials simulation to interpret experimental $I_c$ degradation from microstructural evolution. Monte Carlo transport on tokamak geometry generate neutron spectra, DPA, H/He generation in REBCO. Neutron spectra used to generate recoil spectra of damaged materials. Molecular Dynamics provides insight into material morphology, time and temperature dynamics, spectra and proton/neutron differences.

PHITS
Particle and Heavy Ion Transport code System

Computational framework to investigate irradiation variables (particle, spectra, temperature, magnetic field, etc) on REBCO microstructural evolution.

Can SEM/TEM imaging of defect morphology combined with modeling enable prediction of $I_c$ degradation from primary irradiation conditions?

Primary experimental approach has been cryogenic 1.2 MeV proton irradiation with in-situ $I_c(T)$ characterization of REBCO tapes.

Cryogenic proton irradiation (down to 20 K) with in-situ critical current testing and thermal annealing capability emulates irradiation of operating REBCO magnets at 20 K:
- Captures radiation damage dynamics at magnet op. temperature
- Provides $I_c$ degradation without effects of room temp. annealing
- Provides data on post-cryogenic irradiation annealing recovery of $I_c$
- Upgrade underway to provide 5T magnet for $I_c(B,T,\theta)$ characterization to capture angle-dependent effects in advanced pinning REBCO

What is the full effect of T? How does it compare to 300K? Come to ASC 2022 to find out!
Developing higher energy (12 MeV) cryogenic proton irradiation of bulk material specimens and commercial REBCO tapes (2023)

- Ionetix 12 MeV superconducting proton cyclotron provides irradiation of bulk materials [1,2]
  - Presently utilize 300K -> 800K irradiation targets
  - Proposing to upgrade to 20K -> 300 K target useful for REBCO and other cryogenic magnet materials

- 12 MeV protons provide O(100s) um of uniform radiation damage in bulk specimens such that macroscopic material properties can be obtained as function of radiation dose
  - Structural materials (steels, OHFC copper, etc.)
  - Epoxies, resins, insulation (20K -> 300K)
  - Commercial REBCO tapes w/ in-situ Ic(B,T) testing

New experiment will enable flexible cryogenic neutron irradiation with matched energy spectra at MIT Reactor (2023/2024)

- MIT Reactor is a 6 MW HEU-fueled research reactor located adjacent to the PSFC laboratories on main campus

- Historically, the problem of cryogenic irradiation is dealing with the high thermal loads placed on in-core samples

- We are working with MITR to recommission their “fast fission convertor” capability and to use for cryogenic irradiation at 20 K and with fluxes of $\sim 10^{23} \text{n/m}^2/\text{yr}$
  - Utilize U235 plates external to the core to generate high fluence of fast neutrons in space adjacent to the power core
  - Eliminates high thermal load from reactor core
  - Provides significant space for irradiation but also \( Ic(B,T,A) \) characterization with a high-field external research magnet

- Opportunities for REBCO but other magnet materials experiencing similar lifetime fluences of $\sim 5 \times 10^{22} \text{n/m}^2$
  - OHFC copper, epoxies/insulation, instrumentation, etc.
Accelerating understanding of radiation damage in REBCO

While substantial progress has been made, understanding performance of REBCO under irradiation requires new facilities and experimental capabilities that emulate superconducting magnet operating conditions under irradiation.

New facilities at MIT are enabling cryogenic proton and neutron irradiation and testing of REBCO and magnet materials under higher fidelity conditions.

High level summary of some things we have learned to date:

• Irradiation particle type(s), energy spectra, and temperature matter
• Post-irradiation $I_c(B,T,A)$ characterization must be done in relevant regimes to capture substantial changes from field, temperature, and angle
• The sample’s thermal history is critical to understanding damage evolution as well as potential to recover with annealing
