

# E-CLOUD Build-up in Grooved Chambers

Marco Venturini

*Center for Beam Physics, LBNL*

ECL2 -- CERN, 1-2 March 2007

# Outline of work

- ⌞ Augment existing version of POSINST to model e-cloud build-up in the presence of grooved walls
  - Electron orbits are properly followed and collisions located on the groove surface where they occur but ...
  - ... when solving the Poisson equation for the electron self-field the boundaries are those of the smooth chamber (field enhancement at the groove edges not accounted)
- ⌞ Features implemented so far:
  - Rectangular chamber cross section
  - Grooves are placed on top and bottom of wall
  - (Isosceles) triangular grooves with option to account for rounded tips
- ⌞ Motivations:
  - Characterization of e-cloud dynamics more from 'first principles' instead of passing through an intermediate calculation of an 'effective' secondary yield for the grooved wall.
  - Validate previous calculations by M.Pivi, G. Stupakov, and L.Wang.
  - Help settle some alleged disagreement with other calculations
  - Provide modeling tools for ongoing and future measurements

# Calculations done so far:

- ↖ Parameter choice specific for the ILC-DR dipoles.
  - Input deck for POSINST provided by M.Pivi with setting used for previous smooth-chamber DR simulations
- ↖ Exploration of dependence of e-cloud build up on:
  - Groove **angle** and **height**
  - Radius of the **rounded groove tips**
  - Magnitude of **magnetic field**
- ↖ Contact with previous calculations by extracting and effective SEY (*by comparison with e-cloud build-up curves for smooth chambers*)

# ILC DR basic parameters used in simulations

Beam/dipole parameters:

Dipole magnetic field	0.194 T
Beam sizes in bends	$\sigma_x=0.62$ mm, $\sigma_y=8\mu\text{m}$ , $\sigma_z=6\text{mm}$
Particle/bunch	$N=2 \cdot 10^{10}$

Bunch-train structure parameters:

RF bucket spacing	1.52 ns (=0.46m) [ $f_{RF}=650$ MHz, $C=6.11\text{Km}$ ]
Bunch spacing	6.1 ns (one every four RF buckets)
No. bunches/train	111
Train length	0.68 $\mu\text{s}$ (=204m)

- ⌵ Chamber sizes: 2.3\*2.3 cm (rectangular)
- ⌵ Max SEY (for smooth surface)  $\delta = 1.75$  
- ⌵ Max. no. of macro-e = 20K found to be adequate (i.e. get small noise in longitudinal e-density)

# Geometry of triangular grooves

↖ Geometry of triangular grooves is defined by angle  $\alpha$  and height  $h_g$

↖  $\alpha=0^\circ$  == flat surface

Snapshot of macro-electron distribution in chamber w/ grooves

# E-cloud dependence on groove angle

**E-cloud build-up during bunch-train passage for various  $\alpha$**

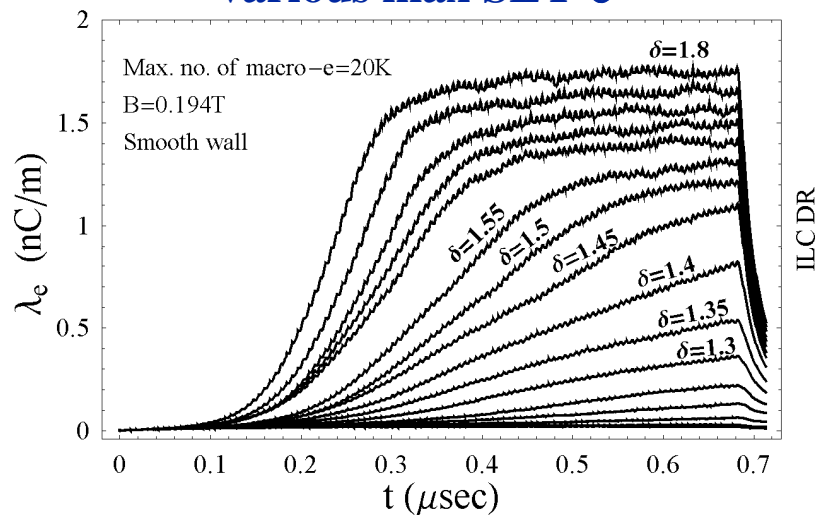

**Max e-cloud density during bunch-train passage vs.  $\alpha$**

⌵ E-cloud density suppressed by a factor  $\sim 200$  for groove angles  $\alpha > 75^\circ$

# Extract an effective SEY from comparison with data from smooth chamber

**E-cloud build-up during bunch-train passage for smooth walls, various max SEY  $\delta$**

**Effective SEY  $\delta$  for various groove angles**

critical angle  
 $\alpha \sim 75^\circ$

- ⌵ The effective SEY for surface with groove angle  $\alpha$  is defined as the SEY of a smooth chamber that results in the same max of e-cloud accumulation

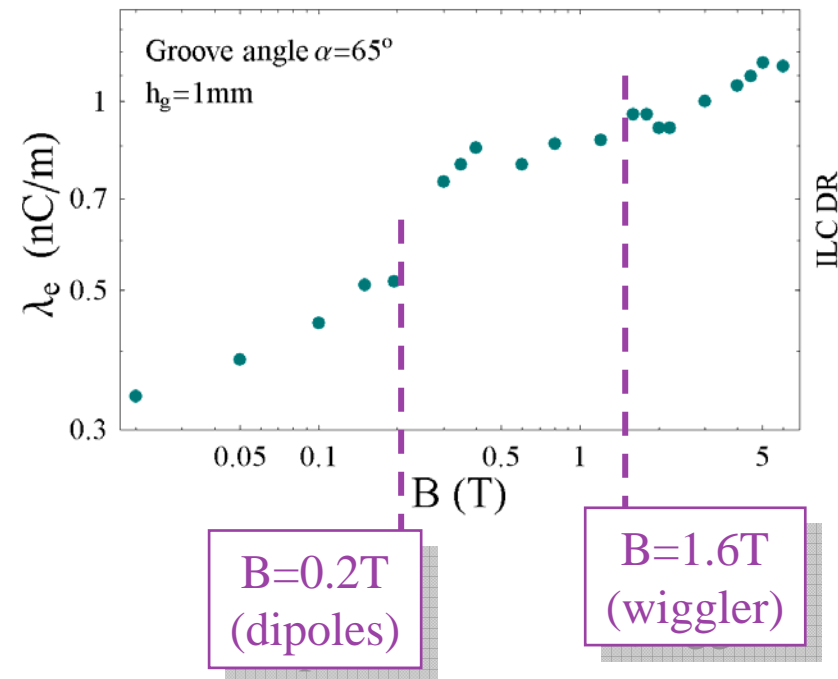

# A higher B-field degrades e-cloud suppression

**E-cloud build-up during bunch-train passage for various B**

**Max e-cloud density vs. B for fixed groove geometry**

↖ A larger cyclotron radius (smaller B-field) enhances chance that secondary electrons may be promptly reabsorbed in wall collision

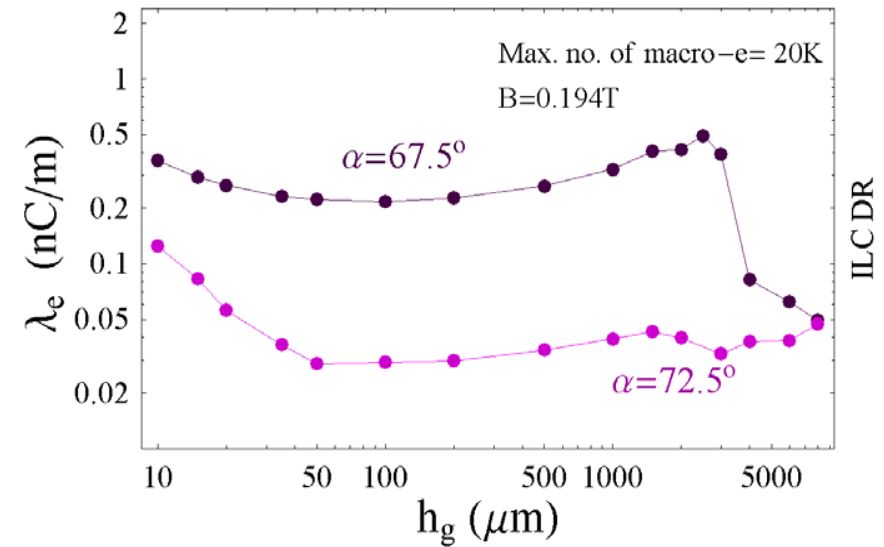

# Dependence on groove height

Max of e-cloud density vs. groove angle  $\alpha$   
for three groove heights  $h_g$

Max of e-cloud density vs.  
height  $h_g$  for two groove angles

⌞ Dependence appears to be generally mild over a large span of height variations

# Triangular grooves with smooth tips

- Smoothing groove tips may be desirable to ease impedance, manufacturing

In present model only the groove edges on the chamber inner side are smoothed

- Geometry of triangular grooves is defined by angle  $\alpha$ , height  $h_g$ , and tip radius  $r_g$

# Smoother tips spoil effectiveness of grooves

Max of cloud density vs. groove-tip radius for two groove height  $h_g$

↖ Spoiling effect of smooth groove-tips can be compensated by making the **grooves deeper**.

Max of cloud density vs. height  $h_g$  for 3 choices of groove-tip radius

↖ Finite groove-tip radius enhances dependence of groove effectiveness on groove height

# Conclusions

- ⌞ Isosceles triangular grooves with steepness angle  $\alpha > 75^\circ$  reduce effective SEY to  $< 1$ 
  - E-cloud build up for a 111 bunch train is reduced by a factor 200.
- ⌞ Results seem about consistent with previous calculations by L.Wang ( $\alpha \sim 70^\circ$  for effective SEY  $< 1$ , *SLAC-PUB-12001*)
- ⌞ A larger magnetic field makes the grooving less effective.
  - In wigglers the groove angle likely to have to be steeper to provide same e-cloud suppression effect as in dipoles
- ⌞ Rounding of the tips spoils e-cloud suppression, which can be compensated by deepening the grooves
