The main drawbacks of normal conducting technology are consumed electricity through Ohmic losses and energy spent on removing extra heat. Superconductors seem to be a better solution. Conventional superconductors need to be cooled below ~5K, consuming large amounts of energy. HTS magnets can operate up to 90K, can be made lighter and can also be nested, resulting in a 7% increase in packing factor and thus luminosity. The system also provides increased flexibility in the optics design, since any phase advance can be chosen with no penalty and there is no requirement for fixed polarity e-/e+ quadrupoles. Moreover, we are hoping to build the system within the same cost envelope as the traditional system (considering the expected cost of HTS tapes in 20 years). FCC-ee is expected to use ~20,000 km of HTS.

The HTS ReBCO tape, due to its particular geometry, cannot be bent in every direction, without breaking or buckling. Thus, a thorough analysis, with the use of Frenet–Serret formulas, was done, resulting in finding a feasible, mathematical solution, according to which a CCT (canted-cosine-theta) magnet can be constructed, without hard-way bending.

The first demonstrator will be a CCT magnet, without, though, rejecting the possibility of using traditional magnets (cosine theta) in the end. The Frenet-Serret framework is expected to provide a feasible solution for traditional magnets as well, but this needs to be further investigated.

The CPES (Cryogenic Power Electronic Supply), a collaboration of ETHZ and PSI, is a parallel project, which focuses on cryogenic power supplies, instead of traditional room temperature ones, and investigates the possibility of moving the power supply inside the cryostat, with the aim of reducing heat losses.

Why HTS?

FCC-ee HTS4 Project

Why HTS?

The main drawbacks of normal conducting technology are consumed electricity through Ohmic losses and energy spent on removing extra heat. Superconductors seem to be a better solution.
