# Container Security:

## What Could Possibly Go Wrong?

Daniel Kouřil

# What is a container?

- fundamentally, a container is just **a running process** controlled by the host kernel
- it is **isolated** from the host and from other processes
- there are different containerization technologies available
  (Docker, Podman, Singularity, LXD, ...)
  - in this tutorial, we will focus mainly on Docker but principles hold for other technologies

# Docker Terminology

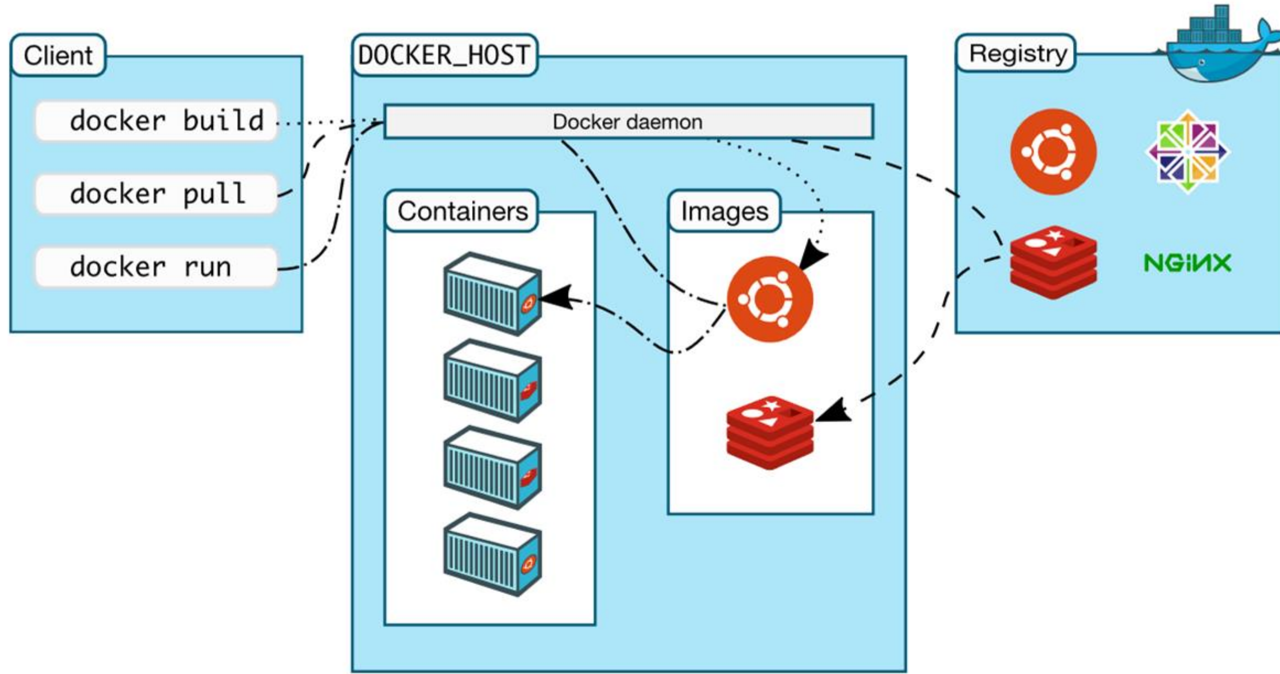
- **Docker container image** - a standalone package of files, which includes everything needed to run an application
  *(code, runtime, system tools, system libraries and settings)*

- an image is usually pulled from a **registry** to a host machine
  *(e.g.* ***DockerHub****)*

- a **Docker container** - a running instance of an image

- a host machine runs the **container engine** (**Docker Daemon**) and manages individual containers

# Docker Architecture



*https://docs.docker.com/get-started/overview/*

# Docker Container Creation

- the image is opened up and the **filesystem** of that image is copied into a **temporary directory structure** on the host
- Docker filesystem is a **stacked file system** of individual layers stacked on “mount”
- the ‘/’ root directory of the container is **mounted and available** on the host, e.g.:

  /var/lib/docker/overlay2/51415bc9cd3ab2c47d218a897516ea2bf0545595fadf4a167ed5cfd3230a5f99/

- changes to the directory **are visible** from both sides (host and container)
- when the container is removed, any changes to its state **disappear** unless “committed” via **dockerd**

```
host# docker ps
CONTAINER ID        IMAGE               COMMAND             CREATED             STATUS              PORTS                    NAMES

# Starting Docker Container Processes

- the container processes are maintained **natively** via the host kernel
- to provide application sandboxing, Docker uses Linux **namespaces** and **cgroups**
- when you start a container with `docker run`, Docker creates **a set of namespaces** and **control groups**, which contain the process(es) started inside the container

# Namespaces

- Docker Engine uses the following namespaces on Linux
  - **PID namespace** for process isolation
  - **NET namespace** for managing/separating network interfaces
  - **IPC namespace** for separating inter-process communication
  - **MNT namespace** for managing/separating filesystem mount points
  - **UTS namespace** for isolating kernel and version identifiers
    (mainly to set the hostname and domainname visible to the process)
  - **User ID** (user) namespace for privilege isolation
- user namespace **must be enabled** on purpose, it is **not** used by default

# PID namespace

- allows the container to establish **separate process trees**
- the complete picture still **visible** from the **host** (running in the “system” namespace)

```
host# docker run -it debian bash
root@3146c2faec9b:/# dash
# ps af

PID  TTY    STAT  TIME  COMMAND
  1  pts/0  Ss    0:00  bash
  6  pts/0  S     0:00  dash
  7  pts/0  R+    0:00  \_ ps af
```

*Host displays all processes*

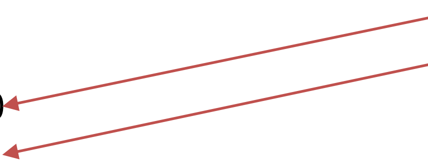
```
 1029 ?      Ssl   7:48   /usr/bin/containerd
28834 ?      Sl    0:00   \_ containerd-shim -namespace moby .........
28851 pts/0  Ss    0:00   \_ bash
28899 pts/0  S+    0:00       \_ dash
```

# User ID (user) Namespace

- enables establishing **separated uid/gid allocations**, decoupled from real identifiers
  - A user process in a the namespace is assigned a ‘local’ identifier that is recognized only inside the namespace
- a **mapping** need to be maintained between uids/gids in the namespace and “global” (real) uids/gids

**Host (real) id’s**

- 0
- 1
- ….
- 100000
- 100001



**id’s in a user namespace**

- 0
- 1

- by default, user namespace is not enabled by Docker, i.e. ***root* in the container is *root* in the host**

# Cgroups I.

- short for **control groups**
- they allow Docker Engine to **maintain available system resources**
- they implement **resource limiting** for different resources (CPU, disk I/O, etc.)
- they help to ensure that a single container can be **assigned only limited resources**
- cgroups are organized in a (tree) **hierarchy** for a given cgroup type

# Cgroups II.

- a process (thread) **may be assigned** one or more cgroup(s)
  - Management possible (e.g.) via the `/sys` pseudo-filesystem (`/sys/fs/cgroup`)
- Example how to set up a cgroup:

```
# create a specific cgroup:
mkdir /sys/fs/cgroup/memory/memory_eaters

# limit the memory usage to 10MB
echo 10000000 > /sys/fs/cgroup/memory/memory_eaters/memory.limit_in_bytes

# enter the new cgroup with the current shell  to apply to limit:
echo $$ > /sys/fs/cgroup/memory/memory_eaters/cgroup.procs
```

# Linux Kernel Capabilities

- capabilities turn the binary “root/non-root” dichotomy into a **fine-grained access control system**
- by default, Docker starts containers with **a restricted set of capabilities**
- Docker supports the **addition** and **removal** of capabilities
- additional capabilities extend the utility but have security implications, too
- a container started with **--privileged flag** obtains **all** capabilities
- running **without --privileged** doesn’t mean the container doesn’t have root privileges!

# I am the root. Or not?

- multiple levels of elevated privileges, from an unprivileged user to full root rights:
  - if user namespace is **enabled**, the root inside a container has no root privileges outside in the host system
    - not available in default Docker setup
  - **by default**, the root in a container has some elevated privileges but restricted by a **set of capabilities**
  - we can **explicitly** add **extra capabilities** to a container on start
  - with the **--privileged flag**, we have full root rights granted

# root may still be limited

```
root# docker run --rm -it debian/ip bash
root@b523a39fcc48:/# iptables -L -n
iptables: Permission denied (you must be root).
root@b523a39fcc48:/#
```

```
root# docker run --rm -it --cap-add=NET_ADMIN debian/ip bash
root@361c51aa11b0:/# iptables -L -n
Chain INPUT (policy ACCEPT)
target     prot opt source               destination

Chain FORWARD (policy ACCEPT)
target     prot opt source               destination

Chain OUTPUT (policy ACCEPT)
target     prot opt source               destination
root@361c51aa11b0:/#
```

# Docker Daemon

- containers and images are maintained by Docker Daemon
- Docker daemon **needs full access** (administrative) to the system
  - Containers can be given all features they need
    - Internally (c.f. iptables before) or externally (port forwarding)
- Docker daemon **provides full access** (administrative) to the system
  - e.g., it allows you to share a directory between the Docker host and a guest container
    - we can start a container where the /host directory is the / directory on your host
- only **trusted users** should be allowed to control your Docker daemon
  - Compare with *root-less* container technology

# Docker interface

- clients communicate with the daemon using an interface
- by default, Docker Daemon listens for requests at a unix domain socket created at **/var/run/docker.sock**
- it is possible to make the Docker Daemon listen on a network interface
- CLI clients have options to specify the endpoint (e.g. over the network)

# Docker vs. chroot command

- a container **isn't instantiated by the user** but the Docker daemon on behalf of the user
- anyone who is allowed to communicate with the Docker Daemon **can manage containers**
- that includes using any **configuration parameters**
    - they can play with binding/mounting files/directories
    - or decide which user id will be used in the container
    - it's not just better chroot

# Container Security

# Threat Landscape

- proper **deployment** and **configuration** requires understanding the technology
- **image management** (integrity and authenticity of the image)
- trust in the **image maintainer** and the **repository operator**
- **malicious images** may be found even in an official registry

*https://unit42.paloaltonetworks.com/cryptojacking-docker-images-for-mining-monero/*

# Usual Best Practice

- especially proper **vulnerability**/**patch management**
- it is often kernel-related and therefore requiring reboot
- proper patch management **extremely important** (couple of vulns over the past few years)
- out of scope for today

# Escaping containers

- a **very general** term
- it does **not necessarily mean controlling the host** system
- severity is determined by the risks
- **data access** (according to the C.I.A triad):
    - Reading (violation of C.)
    - Modifying (violation of I.)
- **executing** code **outside** the container (assigned cgroups and namely namespaces)

# Escaping with containers

- make use of technology to **bypass existing barriers**
  - e.g., mounting a directory to a container
- inject a “hook” that is invoked **by a trusted component** in the system
  - a crontab rule or a kernel “notifier” running command on certain events
  - must run outside the container - APIs (e.g. inotify) won’t help

# Docker-related incidents

- **unprotected access** to Docker Daemon over the Internet
  - revealed by common Internet scans
  - instantiation of malicious containers used for dDoS activities
- **stolen credentials** providing access to the Docker Daemon
  - used to deploy a container set up in a way allowing breaking the isolation
  - the attackers escaped to the host system
  - an deployed crypto-mining software and misused the resources

# Other kernel security features

- it is possible to **enhance Docker security** with systems like TOMOYO, AppArmor, SELinux, etc.
- you can also run the kernel with GRSEC and PAX
- all these extra security features require **extra configuration**

# Cheat Sheets

# Docker Cheat Sheet I.

*start a new container*
docker run IMAGE
docker run --rm IMAGE

*start a new container in interactive mode (e.g. with a shell)*
docker run -it IMAGE bash

*start a new container from an image with a command*
docker run IMAGE command

*start a new container and map a local directory into the container*
docker run -v HOSTDIR:TARGETDIR IMAGE

# Docker Cheat Sheet II.

*show a list of running containers*
docker ps

*show a list of all containers*
docker ps -a

*delete a container*
docker rm CONTAINER

*start a shell inside a running container*
docker exec -it CONTAINER bash

*stop a running container*
docker stop CONTAINER

*resume a stopped container*
docker start CONTAINER

*download an image from a repository*
docker pull IMAGE

*List local images*
docker image ls

*Delete a local image*
docker image rm IMAGE

# Practical Part
