

Introduction to Detector Readout

ISOTDAQ 2012

February, 1 - 8, 2012

Cracow University of Technology and
Institute of Nuclear Physics, Cracow, Poland

Niko Neufeld, CERN-PH

Thanks&disclaimer

- Some material and lots of inspiration for this lecture was taken from lectures B. Jacobson, P. Mato, P. Sphicas, J. Christiansen
- In the electronics part I learned a lot from H. Spieler (see refs at the end)
- I am a (passionate) amateur...

Seeing the data

Physics, Detectors, Electronics

Trigger & DAQ

“Reading” in ATLAS?

Tracking

- Separate tracks by charge and momentum
- Position measurement layer by layer
 - Inner layers: silicon pixel and strips → presence of hit determines position
 - Outer layers: “straw” drift chambers → need time of hit to determine position

Calorimetry

- Particles generate showers in calorimeters
 - Electromagnetic Calorimeter (yellow): Absorbs and measures the energies of all electrons, photons
 - Hadronic Calorimeter (green): Absorbs and measures the energies of hadrons, including protons and neutrons, pions and kaons
- amplitude measurement required to find deposited charge
- position information provided by segmentation of detector

Muon System

- Electrons formed along the track drift towards the central wire.
- The first electron to reach the high-field region initiates the avalanche, which is used to derive the timing pulse.
- Since the initiation of the avalanche is delayed by the transit time of the charge from the track to the wire, the detection time of the avalanche can be used to determine the radial position^(*)

→ **need fast timing electronics**

ATLAS Muon drift chambers have a radius of 3 cm and are between 1 and 6 m long

(*) Clearly this needs some start of time $t=0$ (e.g. the beam-crossing)

Many detectors – One problem

Although these various detector systems look very different, they all follow the same principles:

- Sensors must determine
 1. presence of a particle
 2. magnitude of signal
 3. time of arrival
- Some measurements depend on **sensitivity**, i.e. detection threshold, e.g.: silicon tracker, to detect presence of a particle in a given electrode
- Others seek to determine a *quantity* very **accurately**, i.e. resolution, e.g. : calorimeter – magnitude of absorbed energy; muon chambers – time measurement yields position

All have in common that they are sensitive to:

- signal magnitude
- fluctuations

The “front-end” electronics`

- Front-end electronics is the electronics directly connected to the detector (sensitive element)
- Its purpose is to
 - acquire an electrical signal from the detector (usually a short, small current pulse)
 - tailor the response of the system to optimize
 - the minimum detectable signal
 - energy measurement (charge deposit)
 - event rate
 - time of arrival
 - in-sensitivity to sensor pulse shape
 - digitize the signal and store it for further treatment

Electronics in a nutshell

Physicists stop reading here

- It is well known that

$$d\mathbf{F} = 0$$

$$d\mathbf{G} = \mathbf{J}$$

$$C : \Lambda^2 \ni \mathbf{F} \mapsto \mathbf{G} \in \Lambda^{(4-2)}$$

- “Only technical details are missing”

Click to **LOOK INSIDE!**

Werner Heisenberg, 1958

A physicist is someone who learned
Electrodynamics from Jackson

Computer scientists live digital

- So why bother with this gruesome (analogue) electronics stuff?

- The problem is that Turing machines are so bad with I/O and it is important to understand the constraints of data acquisition and triggering

The bare minimum

- From Maxwell's equations derive
- Ohm's law and power $I = \frac{U}{R} \quad P = U \times I$
- The IV characteristic of a capacitance $Q = C \times V$
- Impedance $Z = R + i\omega L - \frac{i}{\omega C}$

where: Q = charge (Coulomb),
 C = Capacitance (Farad), $U = V$
 = Voltage (Volt), P = Power
 (Watt), I = Current (Ampere), ω =
 frequency

The read-out chain

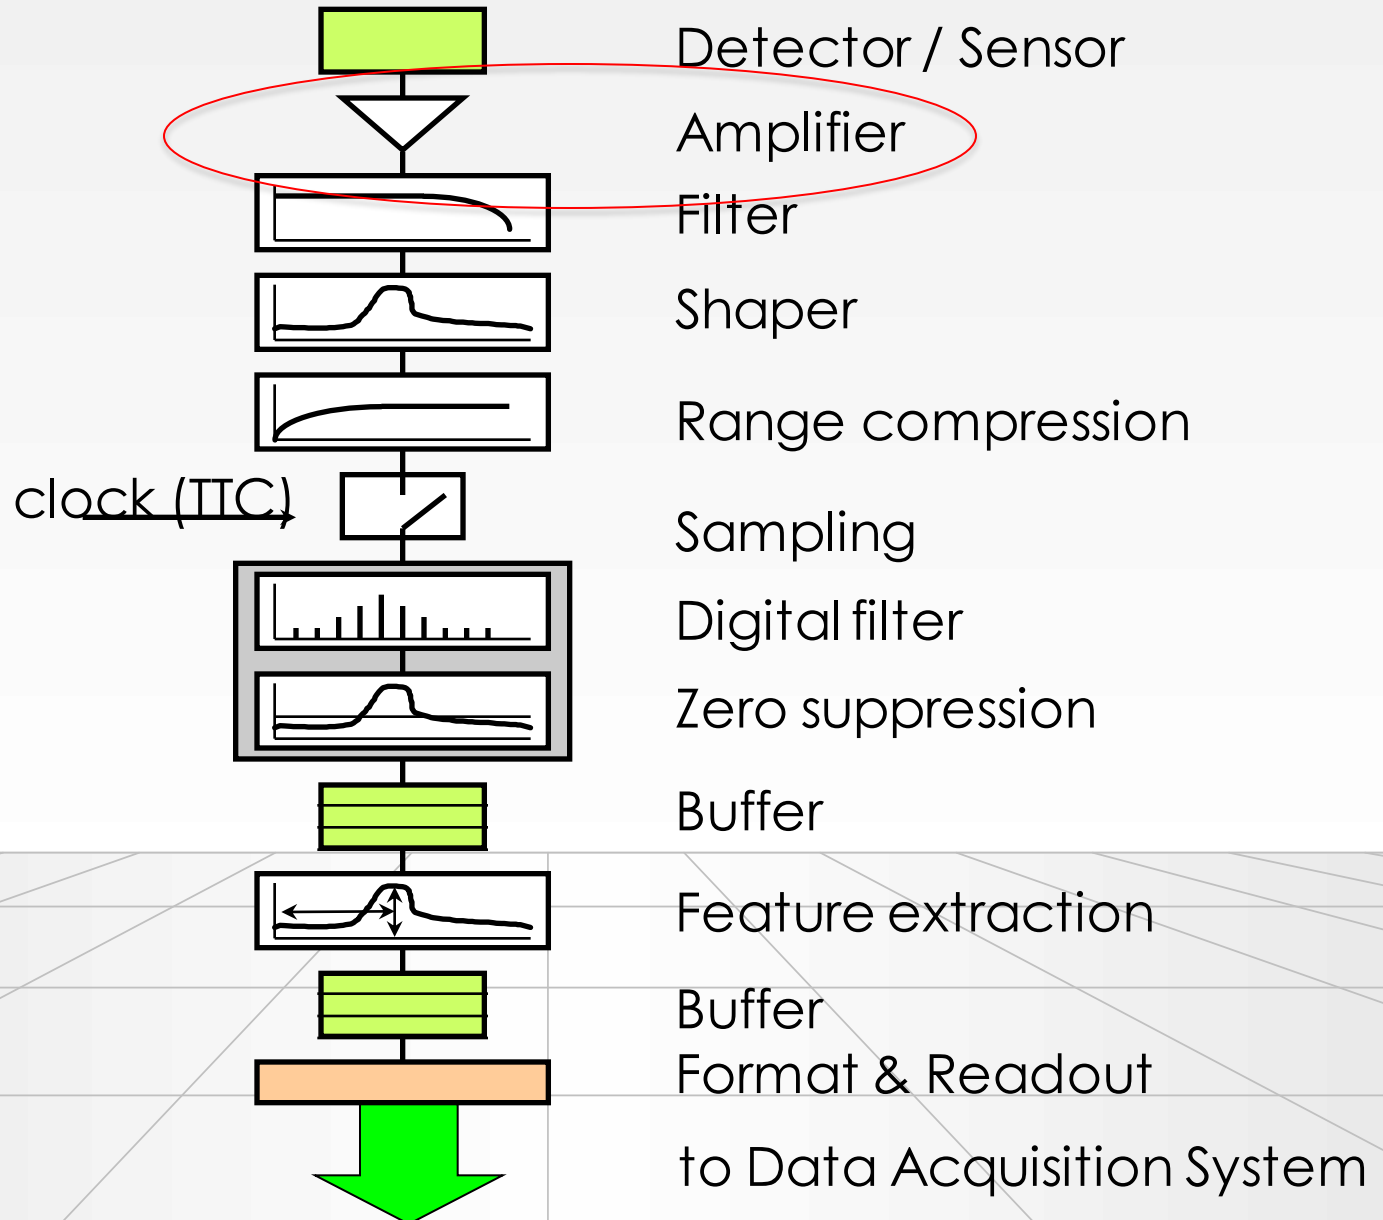

The signal

- The signal is usually a small current pulse varying in duration (from ~ 100 ps for a Si sensor to $O(10)$ μ s for inorganic scintillators)
- There are many sources of signals. Magnitude of signal depends on deposited signal (energy / charge) and excitation energy

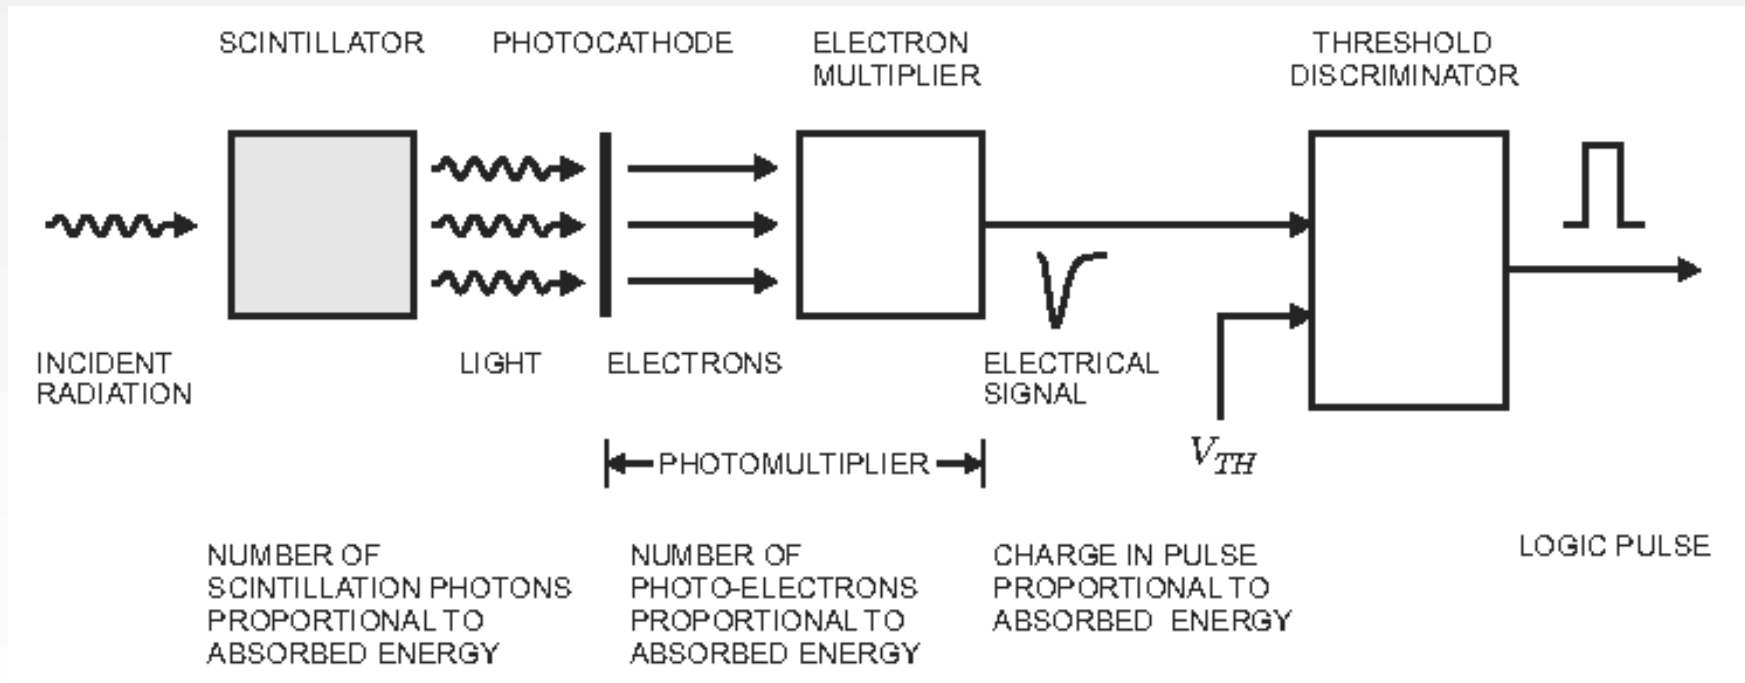

$$S = \frac{E_{absorbed}}{E_{excitation}}$$

Signal	Physical effect	Excitation energy
Electrical pulse (direct)	Ionization	30 eV for gases 1- 10 eV for semiconductors
Scintillation light	Excitation of optical states	20 – 500 eV
Temperature	Excitation of lattice vibrations	meV

The read-out chain

Example: Scintillator

from H. Spieler "Analog and Digital Electronics for Detectors"

- Photomultiplier has high intrinsic gain (== amplification) → no pre-amplifier required
- Pulse shape does not depend on signal charge → measurement is called *pulse height analysis*

Acquiring a signal

- *Interesting signal is the deposited energy* → need to integrate the current pulse
 - on the sensor capacitance
 - using an integrating pre-amplifier, or
 - using an integrating Analog Digital Converter (ADC)
- The signal is usually very small → need to amplify it
 - with **electronics**
 - by signal multiplication (e.g. photomultiplier, see previous slide)

A first approach

- The detector is essentially a capacitance C_d (This is valid for solid-state detectors! For other detectors the equivalent circuit can have resistive and inductive elements)
- A particles puts Q_s into the detector
- Add an amplifier and amplify V_i

$$V_i = \frac{Q_s}{C_d + C_i}$$

Not so practical!
 Response depends
 on sensor capacitance

Charge sensitive amplification

- Feedback amplifier with gain $-A$
- Assume infinite input impedance \rightarrow no current flows into the amplifier and all signal charge builds up on C_f
- Input signal produces v_i at the input of the amplifier generating $-Av_i$ on output

$$A_Q = \frac{v_o}{Q_i} = \frac{Av_i}{C_f(A+1)v_i} = \frac{A}{A+1} \frac{1}{C_f} \approx \frac{1}{C_f} \quad (A \gg 1)$$

- Charge gain depends only on C_f
- $C_i = C_f \times (A+1)$ needs to be large compared to C_d

$$\frac{Q_i}{Q_s} = \frac{C_i}{C_d + C_i} = \frac{1}{1 + \frac{C_d}{C_i}}$$

How good can we get?

Fluctuations & Noise

Fluctuations and Noise

- There are two limitations to the precision of signal magnitude measurements
 1. Fluctuations of the signal charge due to a an absorption event in the detector
 2. Baseline fluctuations in the electronics (“noise”)
- Often one has both – they are independent from each other so their contributions add in quadrature:

$$\Delta E = \sqrt{\Delta E^2_{fluc} + \Delta E^2_{noise}}$$

- Noise affects all measurements – must **maximize signal to noise ratio S/N ratio**

Signal fluctuation

- A signal consists of multiple elementary events (e.g. a charged particle creates one electron-hole pair in a Si-strip)
- The number of elementary events fluctuates $\Delta N = \sqrt{FN}$ where F is the Fano factor (0.1 for Silicon)
- $\Delta E = E_i \Delta N = \sqrt{FEE_i}$ r.m.s.
 $\Delta E_{FWHM} = 2.35 \times \Delta E_{rms}$

Full Width at Half Maximum (FWHM)

from Wikipedia

FWHM = 2.35σ for a Gaussian distribution

Electronics Noise

- Thermal noise
 - created by velocity fluctuations of charge carriers in a conductor
 - Noise power density per unit bandwidth is constant: white noise → larger bandwidth → larger noise (see also next slide)
- Shot noise
 - created by fluctuations in the number of charge carriers (e.g. tunneling events in a semi-conductor diode)
 - proportional to the total average current

SNR / Signal over Noise

Need to optimize Signal over Noise Ratio (SNR)

SNR and Si-detector capacitance

- For a given signal charge Q_s :

$$V_s = Q_s / (C_d + C_i)$$
- Assume amplifier has an input noise voltage V_n , then

SNR is inversely proportional to total capacitance on the input → thicker sensor gives more signal but also more noise

- $$\text{SNR} = \frac{V_s}{V_n} = \frac{Q_s}{V_n \times (C_n + C_d)}$$

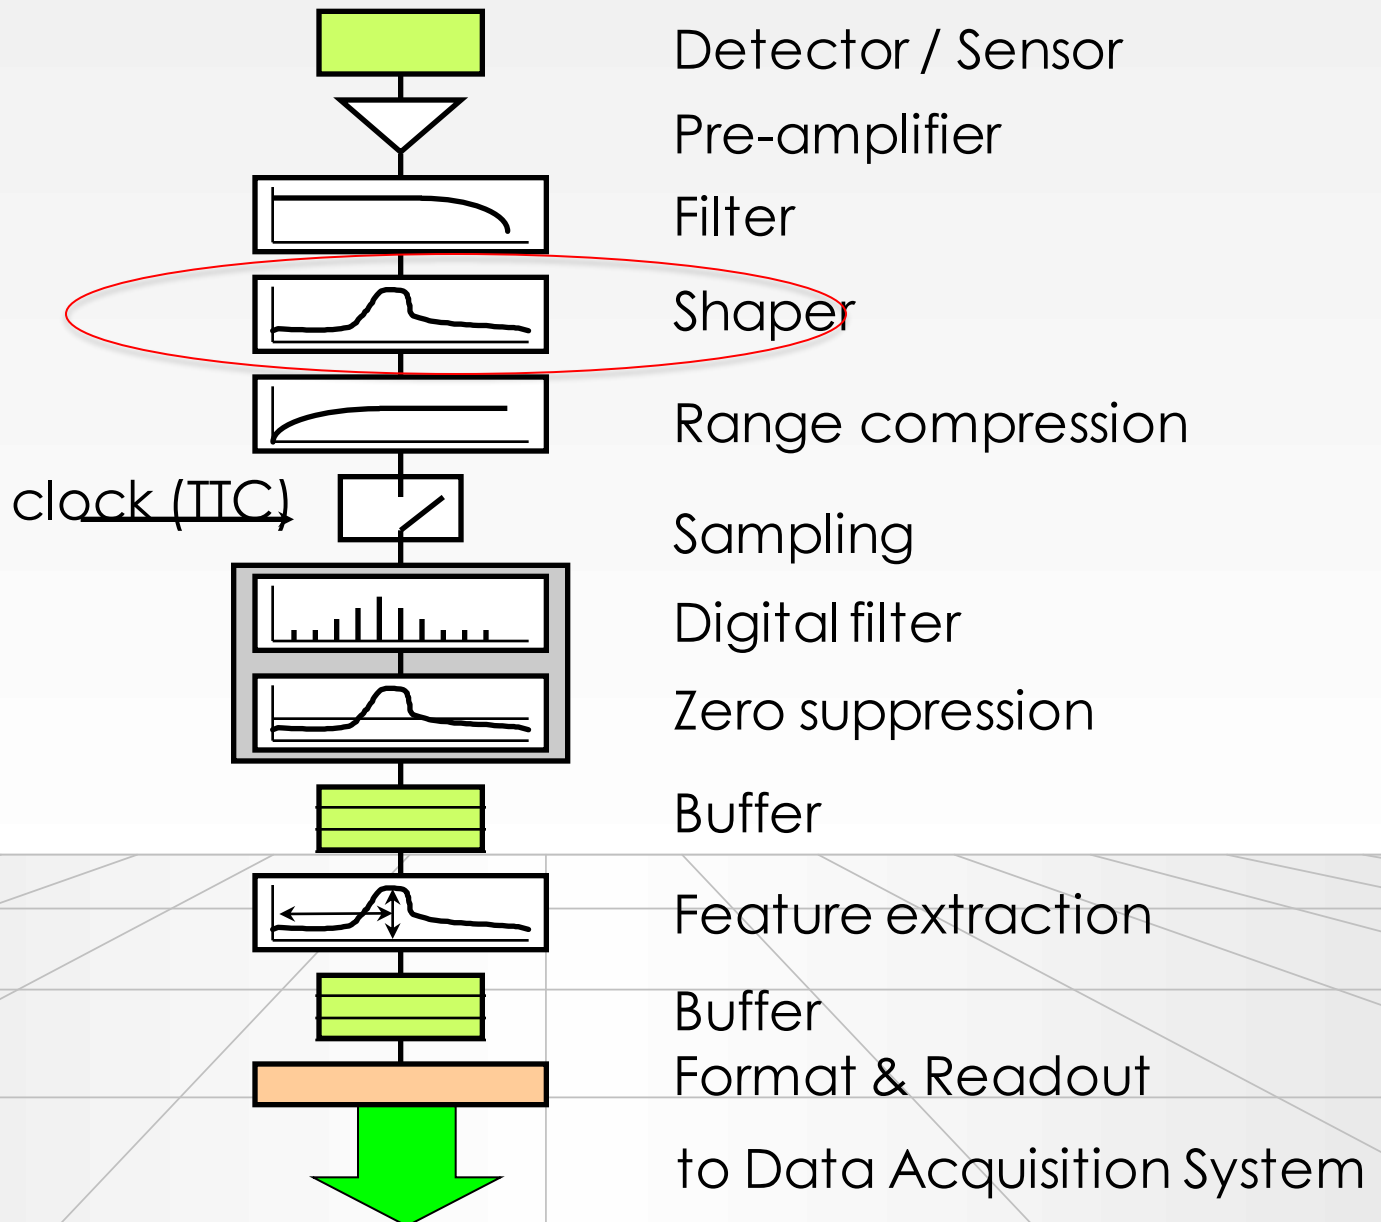

Two important concepts

- The *bandwidth* BW of an amplifier is the frequency range for which the output is at least half of the nominal amplification
- The *rise-time* t_r of a signal is the time in which a signal goes from 10% to 90% of its peak-value
- For a linear RC element (amplifier):

$$BW * t_r = 0.35$$

- For fast rising signals (t_r small) need high bandwidth, but this will increase the noise (see before) → shape the pulse to make it “flatter”

The read-out chain

The pulse-shaper should “broaden”...

- Sharp pulse is “broadened” – rounded around the peak
- Reduces input bandwidth and hence noise

SENSOR PULSE

SHAPER OUTPUT

...but not too much

- Broad pulses reduce the temporal spacing between consecutive pulses
- Need to limit the effect of “pile-up” → pulses not too broad
- As usual in life: a compromise, in this case made out of RC and CR filters

Measuring time

Time measurements

- Time measurements are important in many HEP applications
 - Identification of bunch crossing (LHC: 25ns)
 - Distinguishing among individual collisions (events) in continuous beam like experiments (or very short bunch interval like CLIC: ~250ps)
 - Drift time
 - Position in drift tubes (binary detectors with limited time resolution: ~1ns)
 - Time projection chamber (both good time and amplitude)
 - Time Of Flight (TOF) detectors (very high time resolution: 100ps)
- Time walk: Time dependency on amplitude
 - Low threshold (noise and pedestal limited)
 - Constant fraction discrimination
 - Works quite well but needs good analog delays (cable delay) which is not easy to integrate on chip.
 - Amplitude compensation (done in DAQ CPU's)
 - Separate measurement of amplitude (expensive)
 - Time measurements with two thresholds: 2 TDC channels
 - Time over threshold (TOT): 1 TDC channel measuring both leading edge and pulse width
- Time Over Threshold (TOT) can even be used as a poor mans ADC
 - E.g. ATLAS Pixel

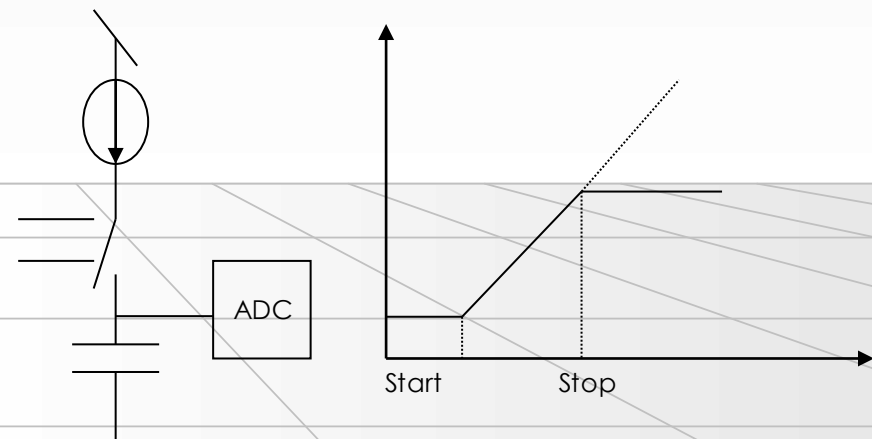

Constant fraction discriminator

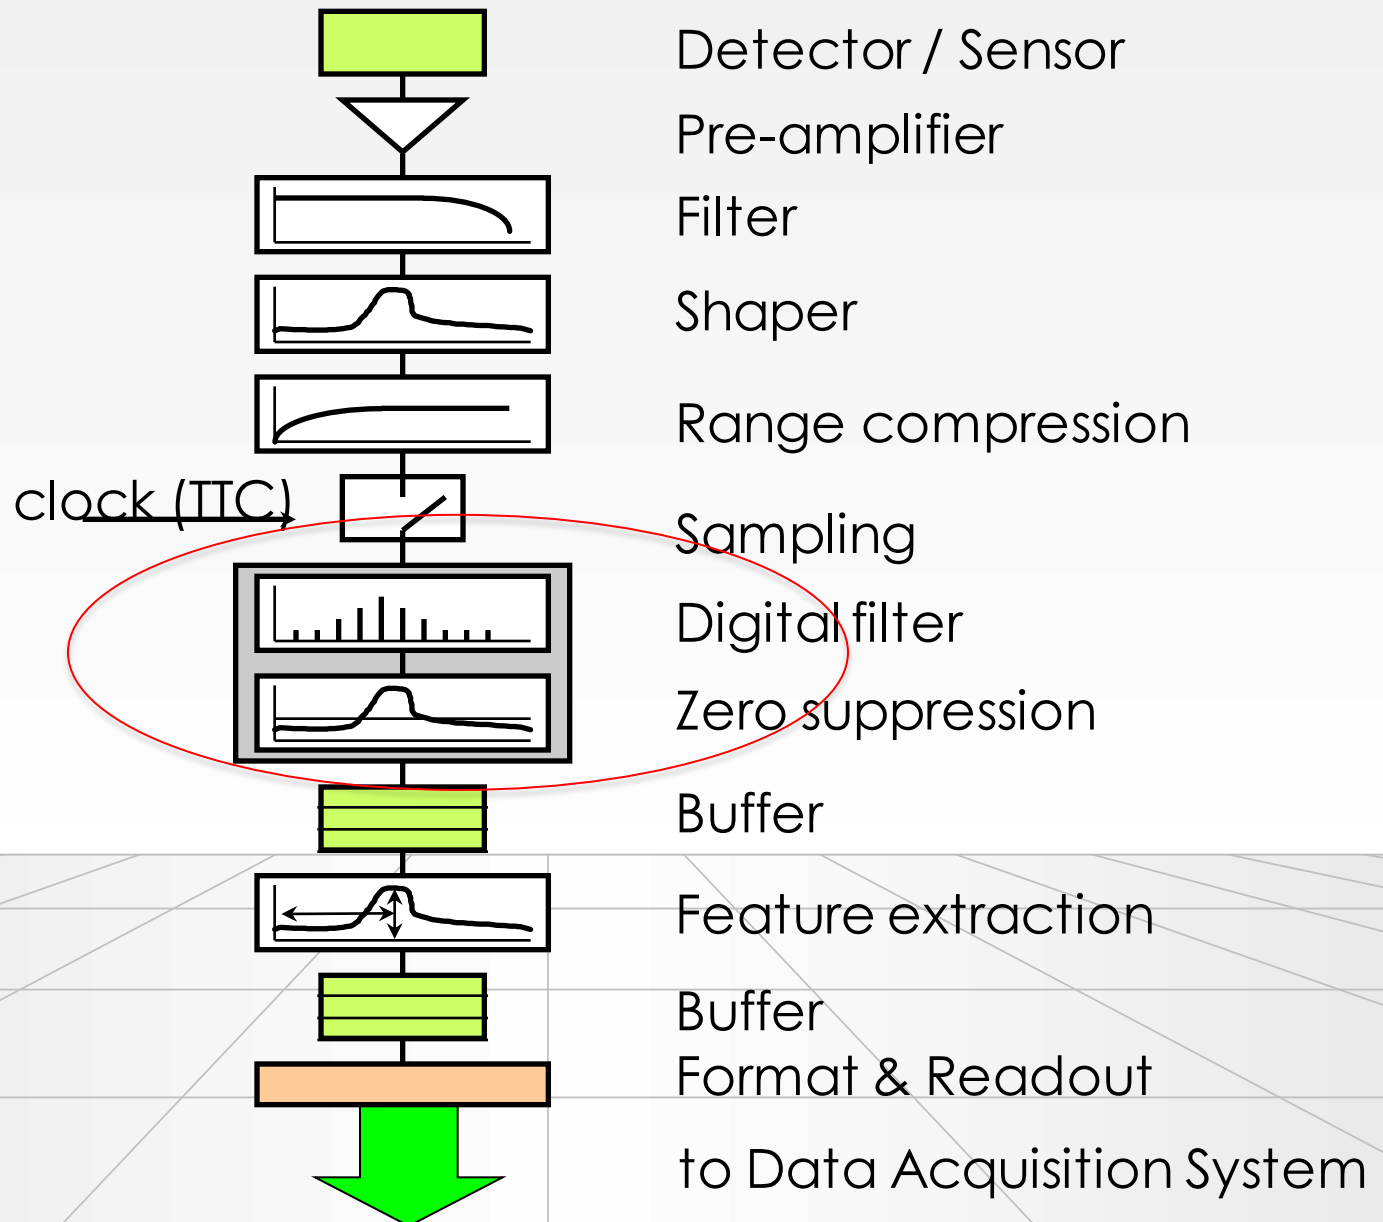

Time to digital conversion

- Counter
 - Large dynamic range
 - Good and cheap time references available as crystal oscillators
 - Synchronous to system clock so good for time tagging
 - Limited resolution: ~ 1 ns
- Charge integration (start – stop)
 - Limited dynamic range
 - High resolution: ~ 1 -100 ps
 - Sensitive analog circuit needing ADC for final conversion.
 - Sensitive to temperature, etc. so often needs in-system calibration
 - Can be combined with time counter for large dynamic range

The read-out chain

Analog/Digital/binary

After amplification and shaping the signals must at some point be digitized to allow for DAQ and further processing by computers

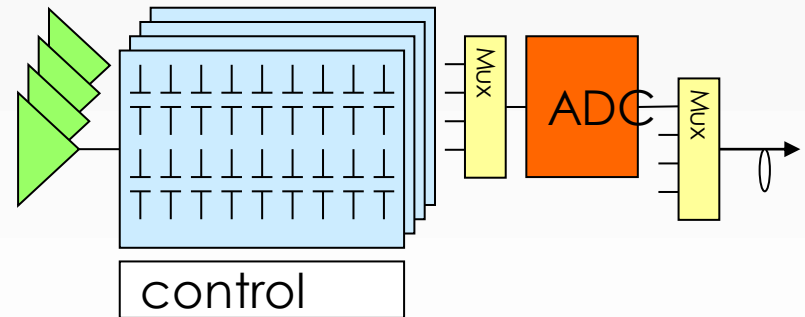

1. Analog readout: analog buffering ; digitization after transmission off detector
2. Digital readout with analog buffer
3. Digital readout with digital buffer

- *Binary*: discriminator right after shaping
 - Binary tracking
 - Drift time measurement

1) Analog memory

2) Analog memory

3) Digital memory

Analog to digital conversion

- There is clearly a tendency to go digital as early as possible
 - This is extensively done in consumer goods
- The “cost” of the ADC determines which architecture is chosen
 - Strongly depends on speed and resolution
- Input frequencies must be limited to half the sampling frequency.
 - Otherwise this will fold in as additional noise.
- High resolution ADC also needs low jitter clock to maintain effective resolution

An important truth

- A solution in detector-electronics can be:
 1. fast
 2. cheap
 3. low-power
- *Choose **two** of the above*: you can't have all three

Cost means:

Power consumption

Silicon area

Availability of radiation hard ADC

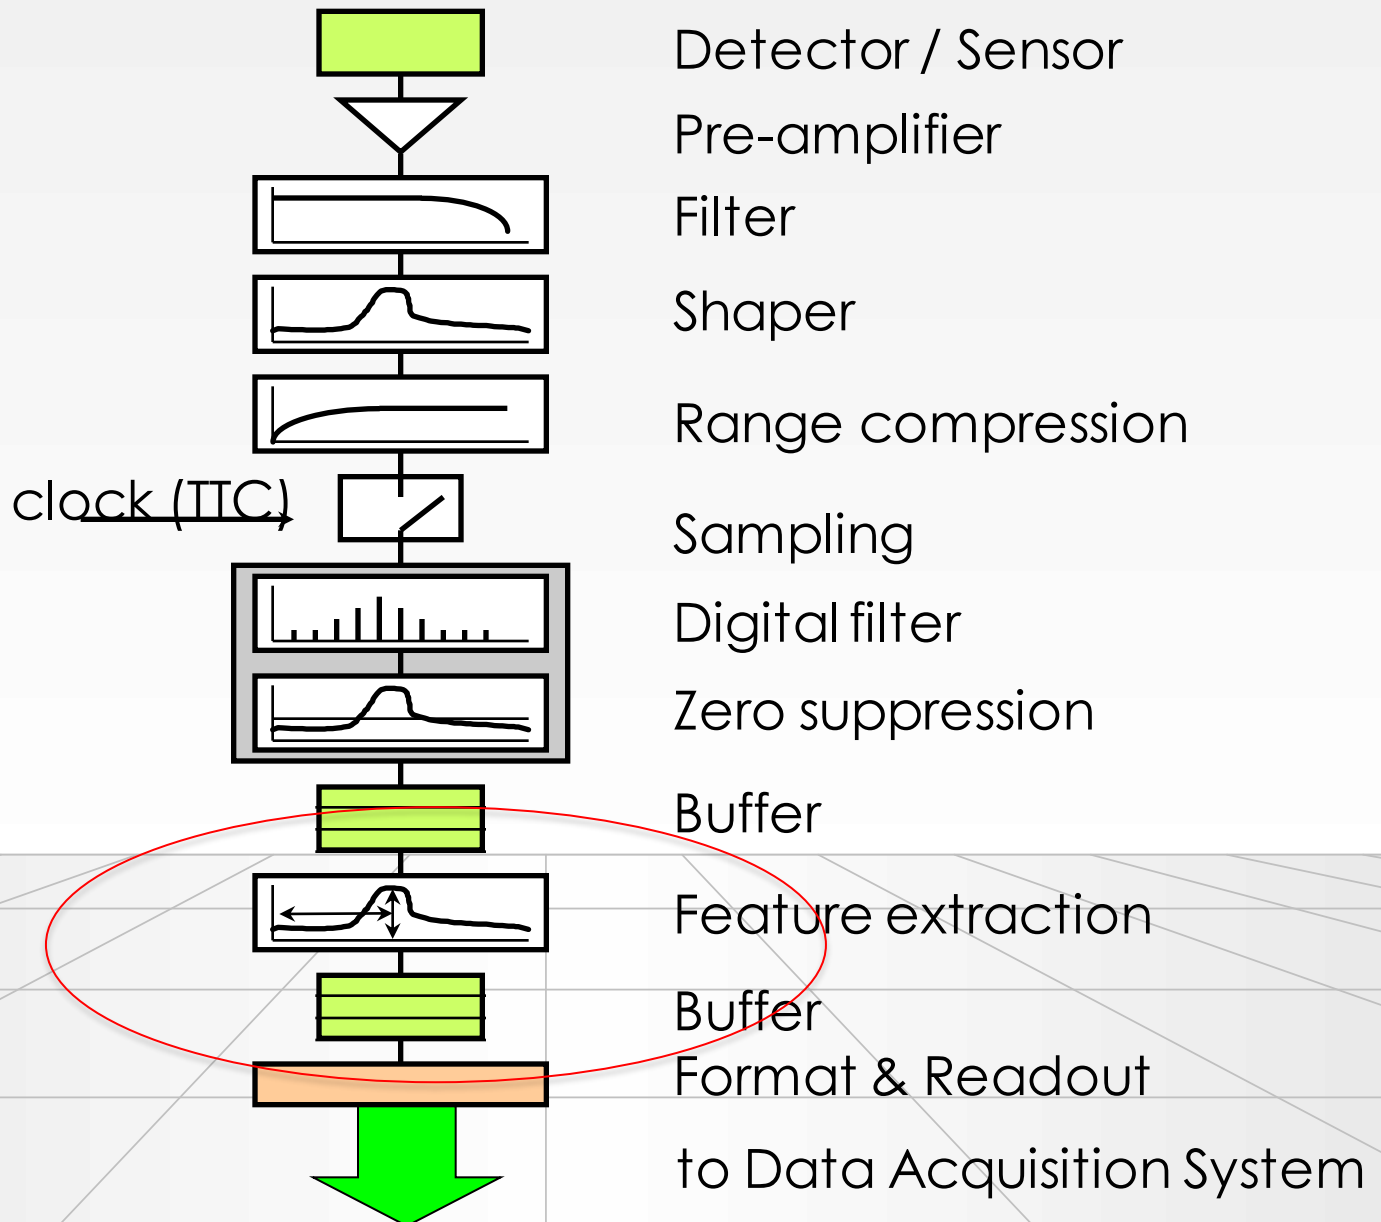

Excursion: zero-suppression

- Why spend bandwidth sending data that is zero for the majority of the time?
- Perform **zero-suppression** and only send data with non-zero content
 - Identify the data with a channel number and/or a time-stamp
 - We do not want to lose information of interest so this must be done with great care taking into account pedestals, baseline variations, common mode, noise, etc.
 - Not worth it for occupancies above ~10%
- Alternative: data compression
 - Huffman encoding and alike
- TANSTAFEL (There Aint No Such Thing As A Free Lunch)
 - Data rates fluctuates all the time and we have to fit this into links with a given bandwidth
 - Not any more event synchronous
 - Complicated buffer handling (overflows)
 - Before an experiment is built and running it is very difficult to give reliable estimates of data rates needed (background, new physics, etc.)

Getting the data out

After shaping, amplifying, digitizing

As usual 😊 what you do depends on many factors:

- Number of channels and channel density
- Collision rate and channel occupancies
- *Triggering*: levels, latencies, rates
- Available technology and cost
- What you can/want to do in custom made electronics and what you do in standard computers (computer farms)
- Radiation levels
- Power consumption and related cooling
- Location of digitization
- Given detector technology

Single integrator

- Simple (only one sample per channel)
- Slow rate (and high precision) experiments
- Long dead time
- Nuclear physics
- Not appropriate for HEP

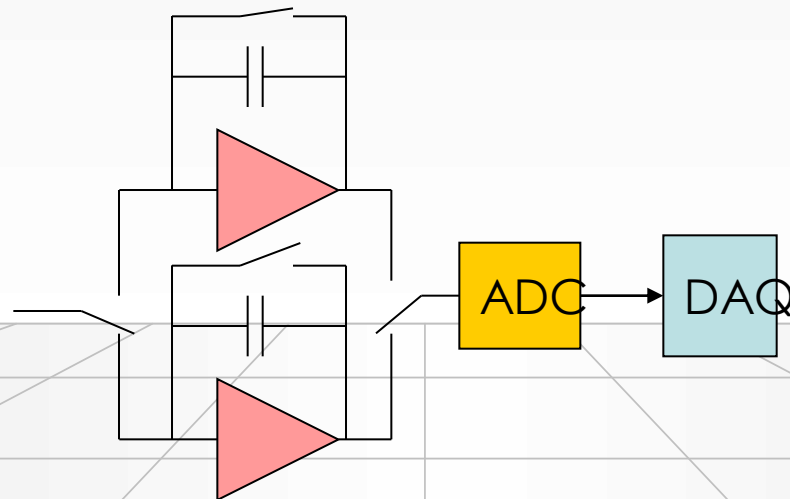

1. Collect charge from event
2. Convert with ADC
3. Send data to DAQ

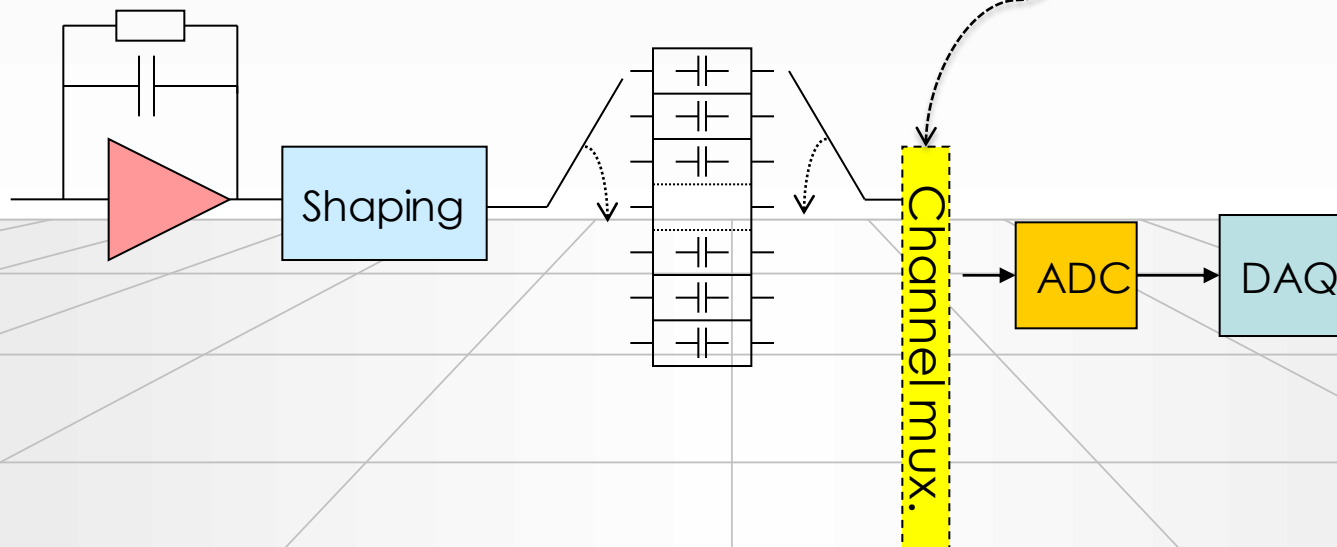

Double buffered

- Use a second integrator while the first is readout and reset
- Decreases dead time significantly
- Still for low rates

Multiple event buffers

- Good for experiments with short spills and large spacing between spills (e.g. fixed target experiment at SPS)
- Fill up event buffers during spill (high rate)
- Readout between spills (low rate)
- ADC can possibly be shared across channels
- Buffering can also be done digitally (in RAM)

Analog buffers

- Extensively used when ADC not available with sufficient speed and resolution or consuming too much power
- Large array of storage capacitors with read and write switches (controlled digitally)
- For good homogeneity of memory
 - Voltage mode
 - Charge mode with Charge integrator for reading
- Examples:
 - Sampling oscilloscopes
 - HEP: CMS tracker, ATLAS calorimeter, LHCb trackers, etc.

Fig. 9 Pedestals for each memory cell in the analog memory. All 32 channels plotted for each of the 192 columns. This plot is of a packaged PACE3 device. 1 ADC count = 0.435mV.

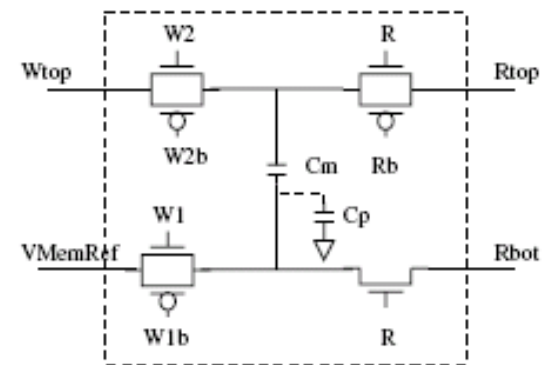

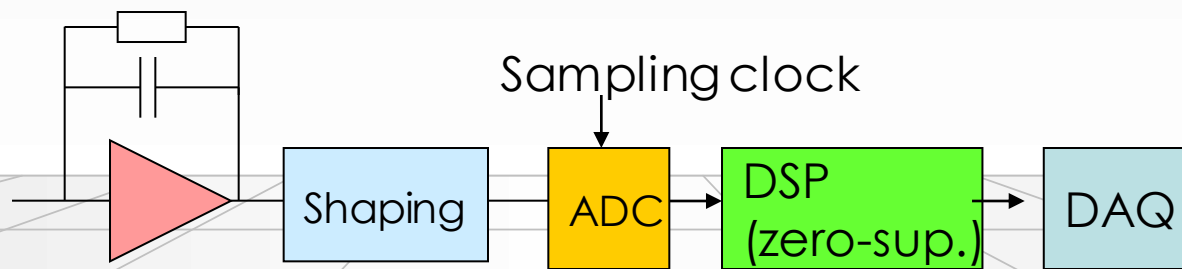

Fig. 5 The analog memory cell of PACE3

Constantly sampled

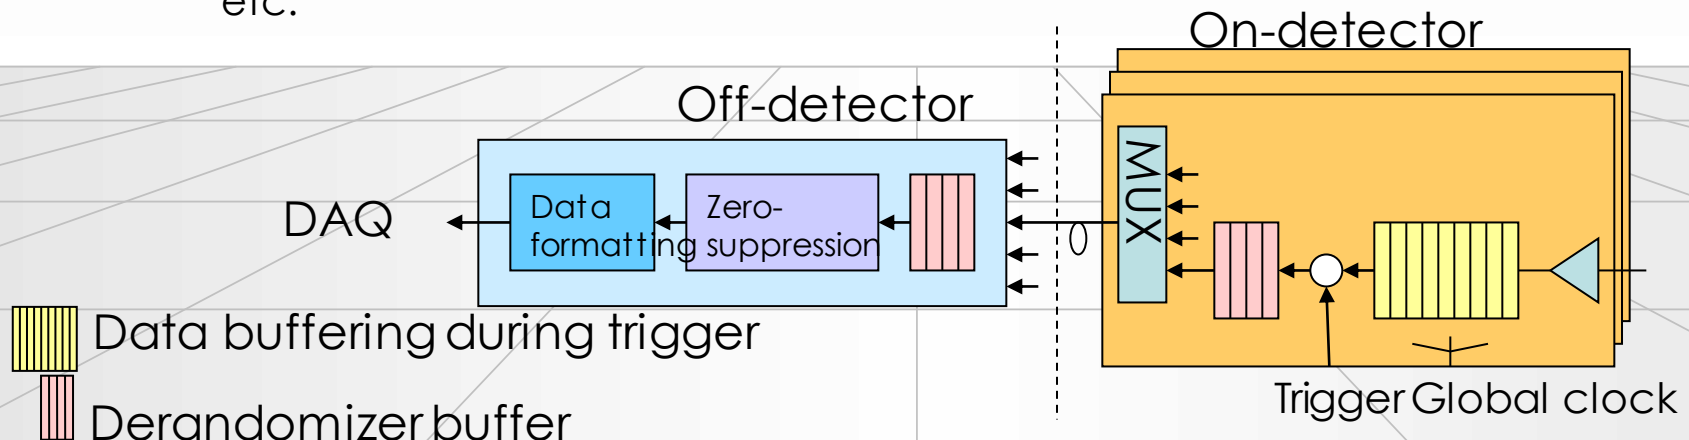

- Needed for high rate experiments with signal pileup
- Shapers and not switched integrators
- Allows digital signal processing in its traditional form (constantly sampled data stream)
- Output rate may be far too high for what following DAQ system can handle

- With local **zero-suppression** this may be an option for future high rate experiments (SLHC, CLIC)

Synchronous readout

- All channels are doing the same “thing” at the same time
- Synchronous to a global clock (bunch crossing clock)
- Data-rate on each link is identical and depends only on *trigger-rate*
- On-detector buffers (*de-randomizers*) are of same size and their occupancy (“how full they are”) depends only on the *trigger-rate*
- ☹ Lots of bandwidth wasted for zero’s
 - Price of links determine if one can afford this
- ☺ No problems if occupancy of detectors or noise higher than expected
 - But there are other problems related to this: spill over, saturation of detector, etc.

Trigger & DAQ (Sneak Preview)

What is a trigger?

01:02.18
02:50.00

D rally game?

An important part
of a Beretta

The most famous
horse in
movie history?

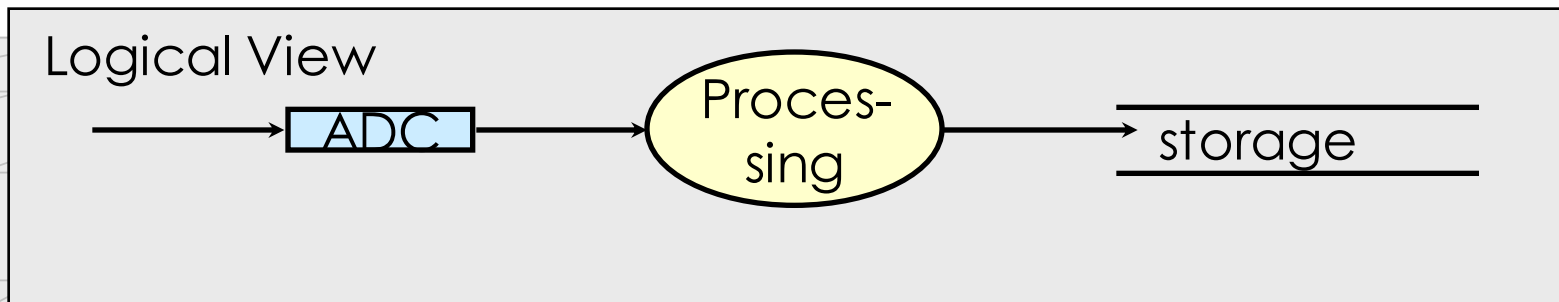

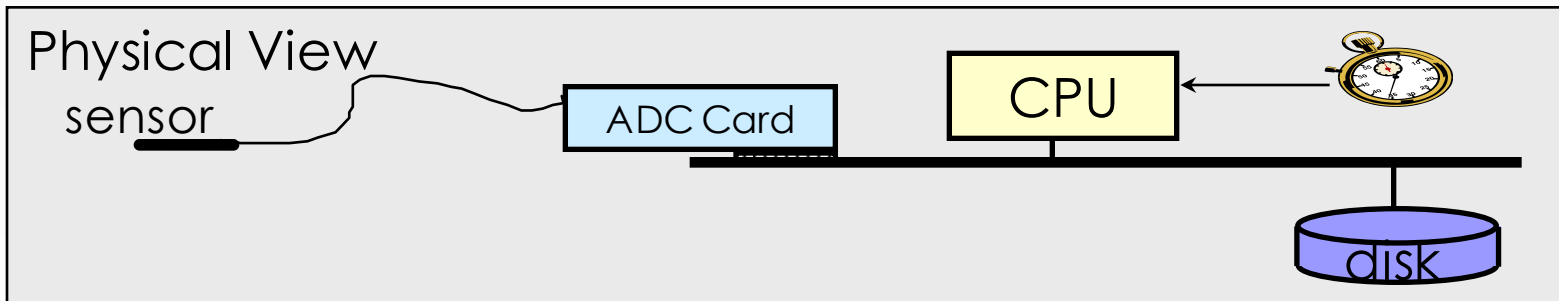

What is a trigger?

Wikipedia: “ **A trigger is a system that uses simple criteria to rapidly decide which events in a particle detector to keep when only a small fraction of the total can be recorded. “**

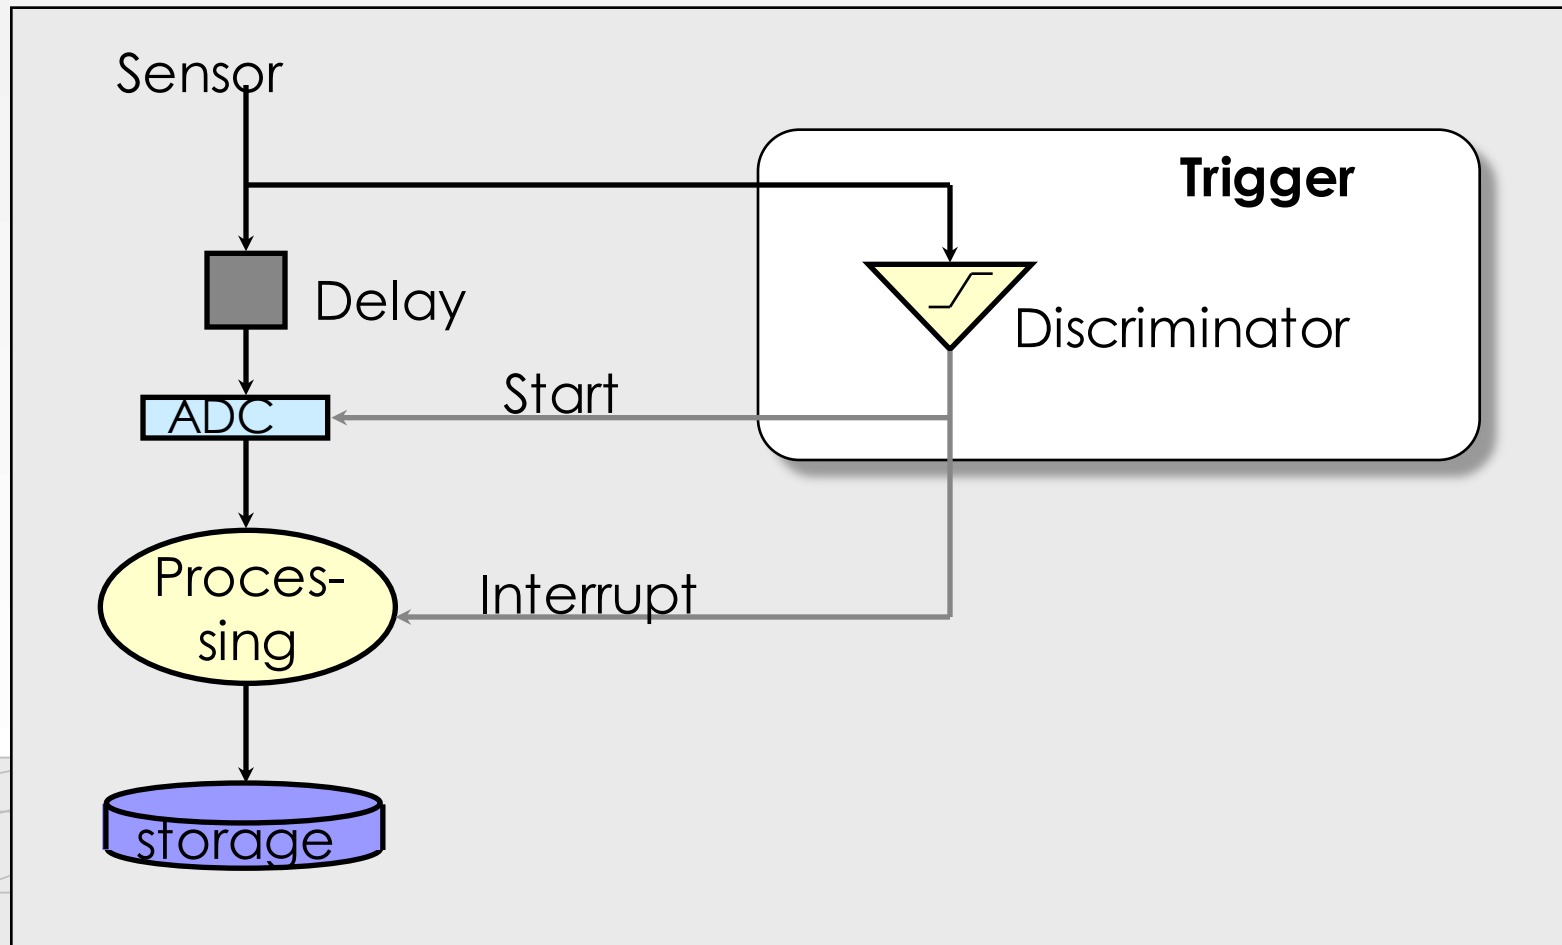

Trigger

- Simple
- Rapid
- Selective
- When only a small fraction can be recorded

Trivial DAQ

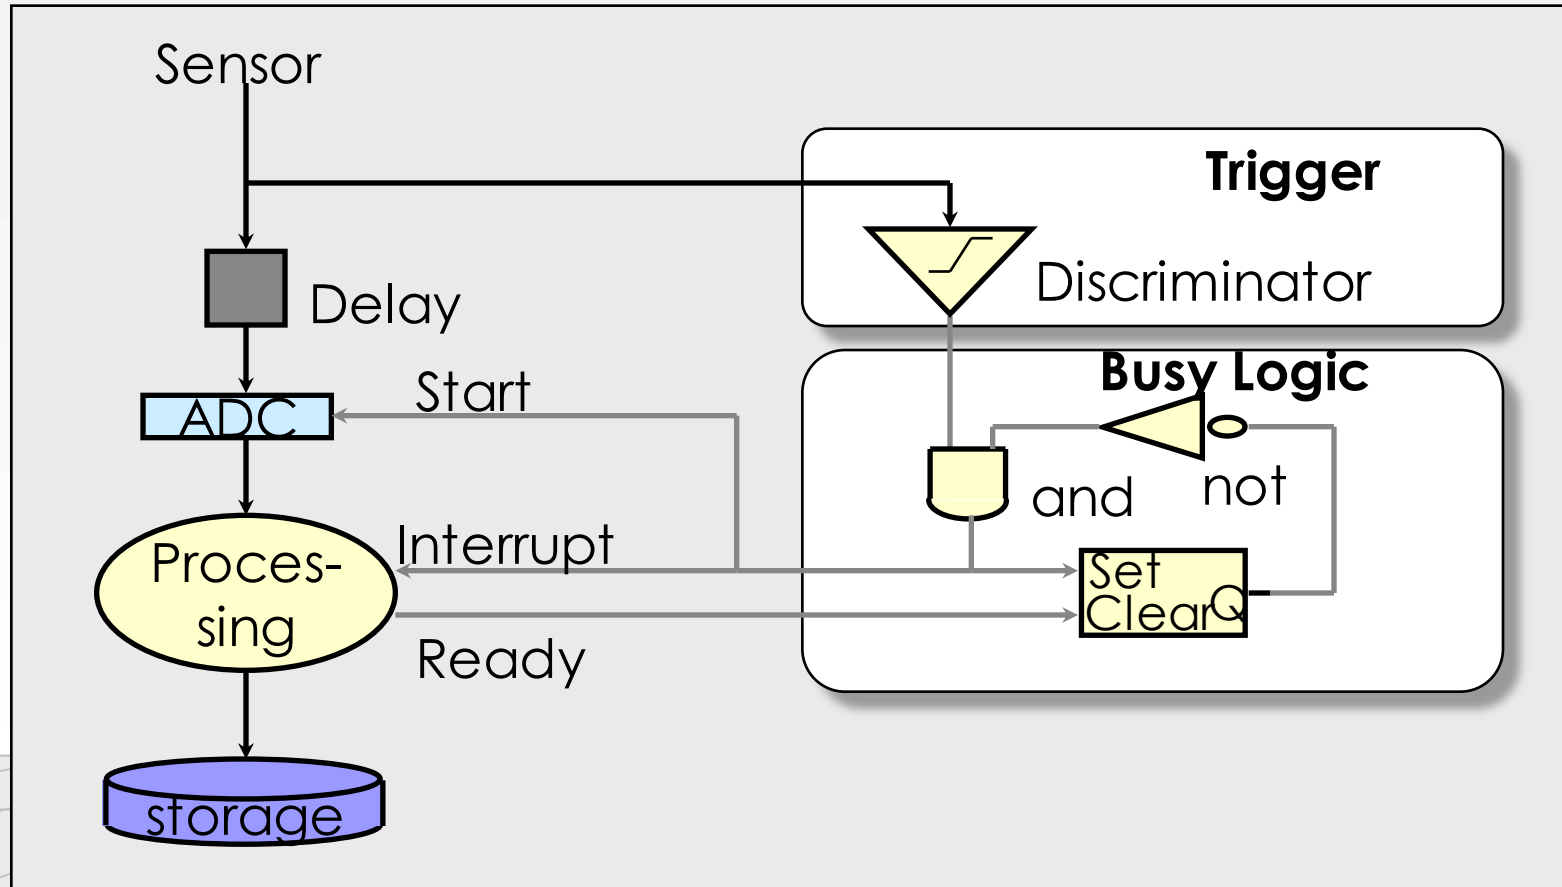

Trivial DAQ with a real trigger

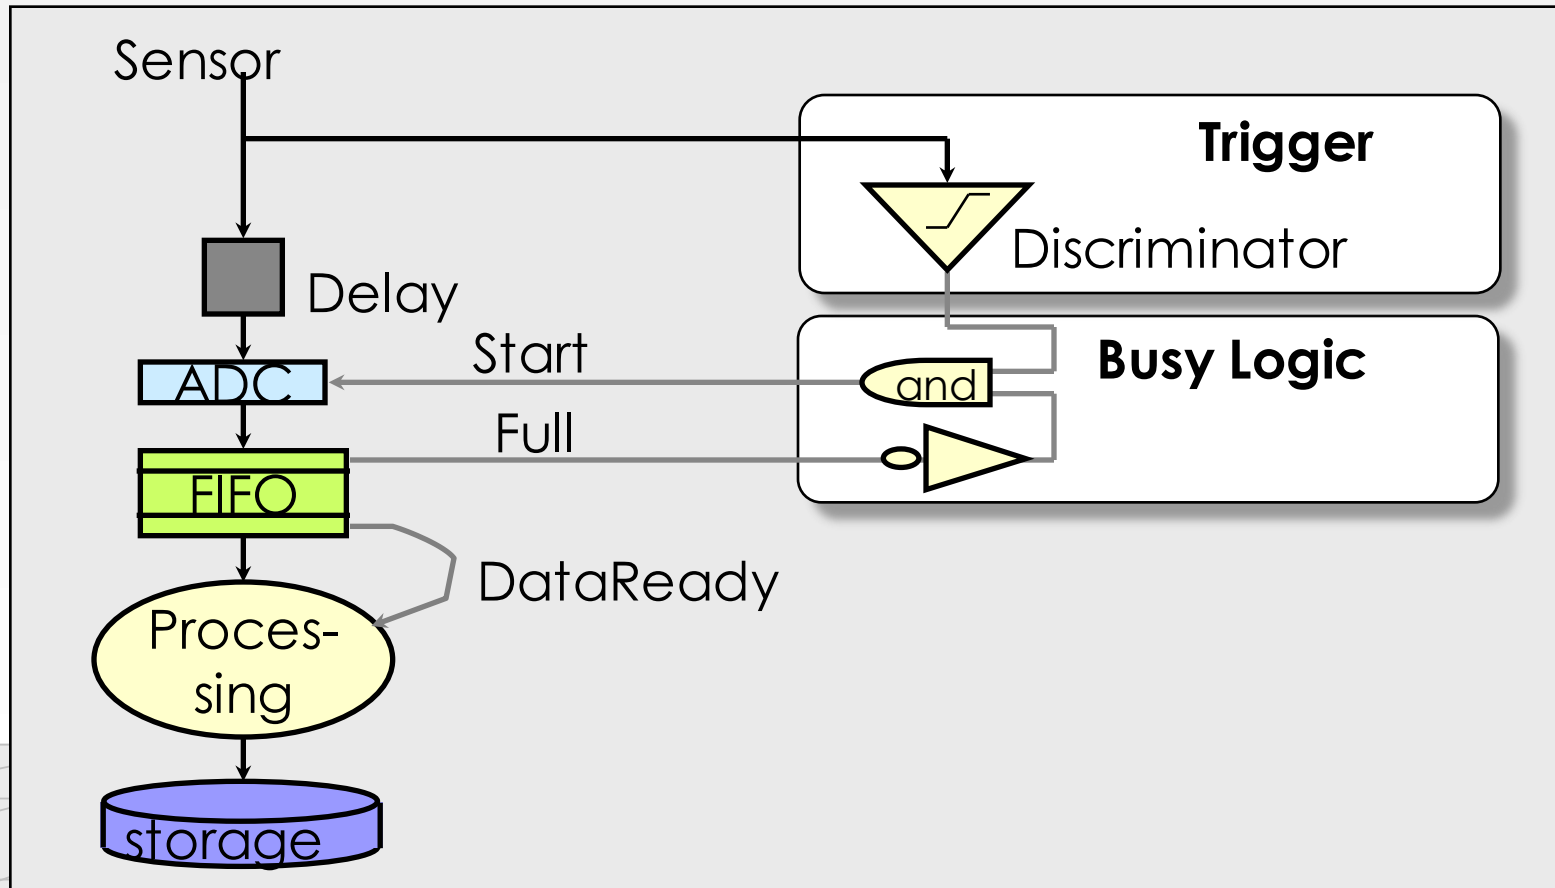

What if a trigger is produced when the *ADC* or *processing* is busy?

Trivial DAQ with a real trigger 2

Deadtime (%) is the ratio between the time the DAQ is *busy* and the total time.

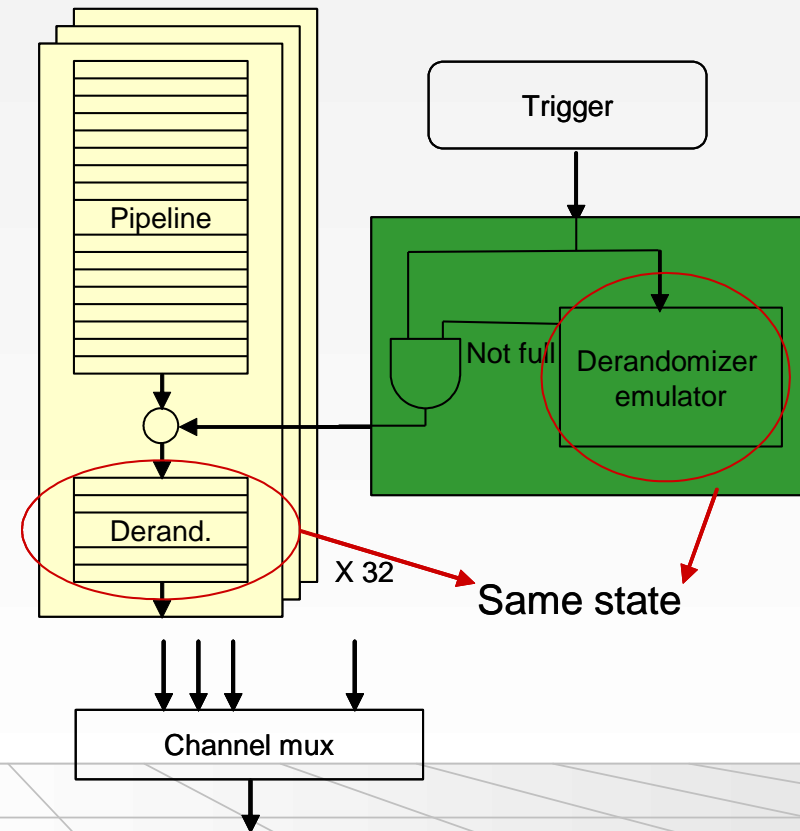

Trivial DAQ with a real trigger 3

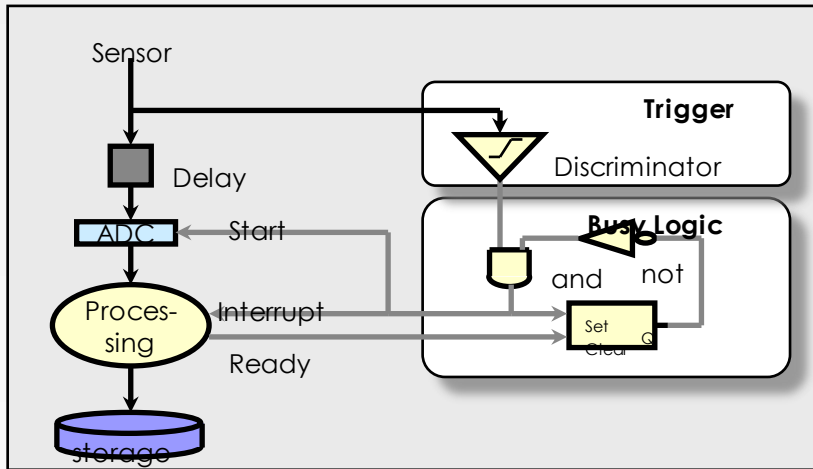

Buffers are introduced to de-randomize data, to decouple the data production from the data consumption. **Better performance.**

Trigger rate control

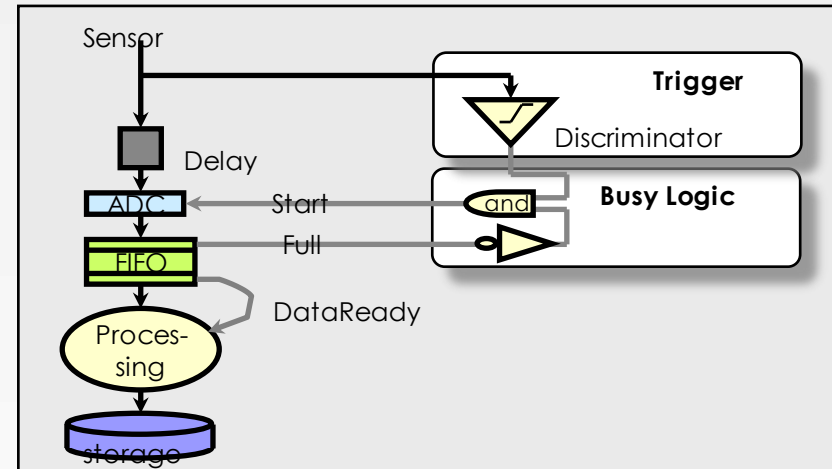

- Trigger rate determined by physics parameters used in trigger system:
 - 1 kHz – 1MHz
 - The lower rate after the trigger allows sharing resources across channels (e.g. ADC and readout links)
- Triggers will be of random nature i.e. follow a Poisson distribution → a burst of triggers can occur within a short time window so some kind of rate control/spacing is needed
 - Minimum spacing between trigger accepts → dead-time
 - Maximum number of triggers within a given time window
- **Derandomizer** buffers needed in front-ends to handle this
 - Size and readout speed of this determines effective trigger rate

Effect of de-randomizing

The system is *busy* during the ADC conversion time + processing time until the data is written to the storage

The system is *busy* during the ADC conversion time if the FIFO is not full (assuming the storage can always follow!)

System optimisation: LHCb front-end buffer

L0 Derandomizer loss vs Read out speed

Trigger latency
Fixed to 4 μ s in LHCb

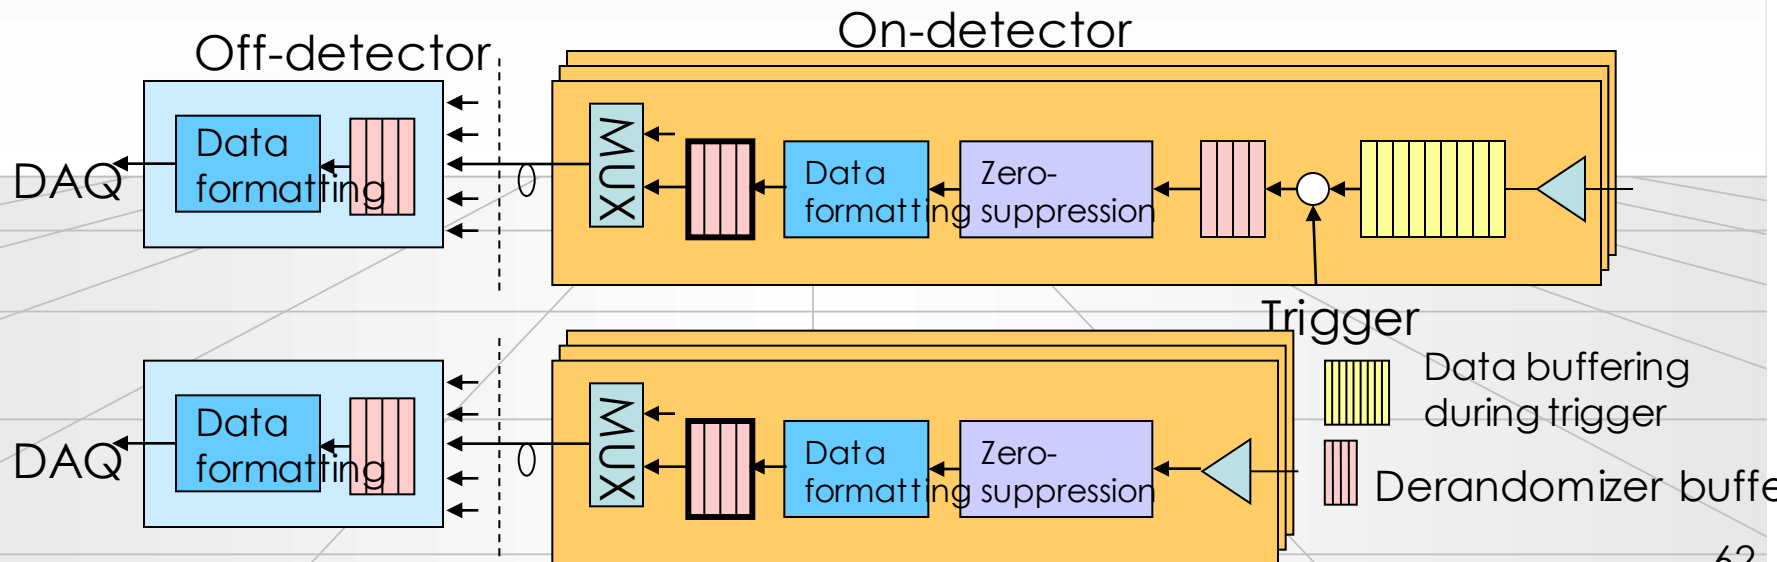

Working point for LHCb
 Max readout time: 900 ns
 Derandomzier depth:
 16 events
 → 1 MHz maximum trigger
 accept rate

Derandomiser size [events]

Asynchronous readout

- Remove zeros on the detector itself
 - Lower average bandwidth needed for readout links Especially interesting for low occupancy detectors
- Each channel “lives a life of its own” with unpredictable buffer occupancies and data are sent whenever ready (**asynchronous**)
- In case of buffer-overflow a truncation policy is needed → **BIAS!!**
 - Detectors themselves do not have 100% detection efficiency either.
 - Requires sufficiently large local buffers to assure that data is not lost too often (Channel occupancies can be quite non uniform across a detector with same front-end electronics)
- DAQ must be able to handle this (buffering!)
- Async. readout of detectors in LHC: ATLAS and CMS muon drift tube detectors, ATLAS and CMS pixel detectors, ATLAS SCT, several ALICE detectors as relatively low trigger rate (few kHz).

To the DAQ

- Large amount of data to bring out of detector
 - Large quantity: ~100k in large experiment
 - High speed: Gbits/s
- Point to point unidirectional
- Transmitter side has specific constraints
 - Radiation
 - Magnetic fields
 - Power/cooling
 - Minimum size and mass
 - Must collect data from one or several front-end chips
- Receiverside can be commercially available module components (use of standard link protocols when ever possible)

An example: the LHCb Vertex detector and its readout IC beetle

- 172k Channels
- Strips in R and ϕ projection ($\sim 10\mu\text{m}$ vertex resolution)
- Located 1 cm from beam
- Analog readout (via twisted pair cables over 60m)

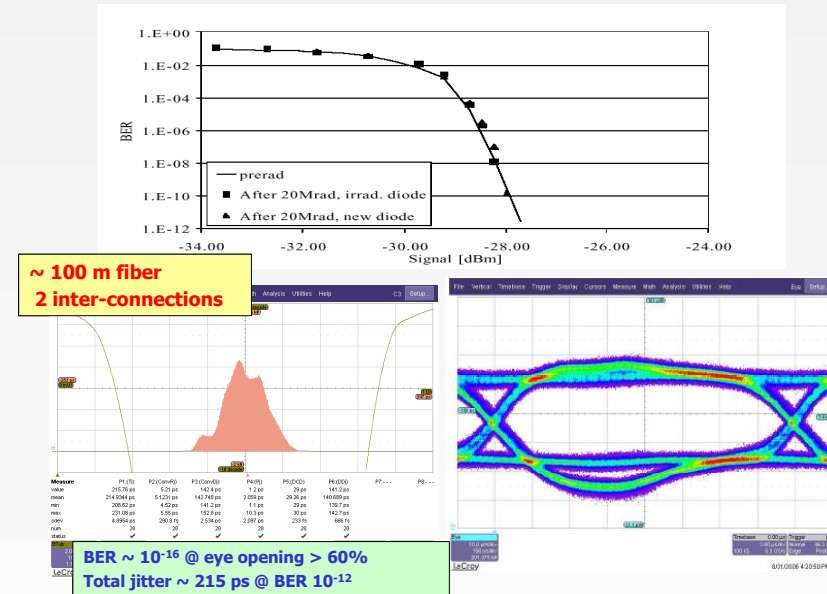

Interaction region

$\sim 1\text{m}$

Digital optical links

- High speed: 1 GHz - 10GHz – 40GHz
- Extensively used in telecommunications (expensive) and in computing (“cheap”)
- Encoding
 - Inclusion of clock for receiver PLL’s
 - DC balanced
 - Special synchronization characters
 - Error detection and or correction
- Reliability and error rates strongly depending on received optical power and timing jitter
- Multiple (16) serializers and deserializers directly available in modern high end FPGA’s.

DAQ interfaces / Readout Boards

- Front-end data reception
 - Receive optical links from multiple front-ends: 24 - 96
 - Located outside radiation
- Event checking
 - Verify that data received is correct
 - Verify correct synchronization of front-ends
- Extended digital signal processing to extract information of interest and minimize data volume
- Event merging/building
 - Build consistent data structures from the individual data sources so it can be efficiently sent to DAQ CPU farm and processed efficiently without wasting time reformatting data on CPU.
 - Requires significant data buffering
- High level of programmability needed
- Send data to CPU farm at a rate that can be correctly handled by farm
 - 1 Gbits/s Ethernet (next is 10Gbits/s)
 - In house link with PCI interface: S-link

Requires a lot of fast digital processing and data buffering: **FPGA's**, DSP's, embedded CPU

Use of ASIC's not justified

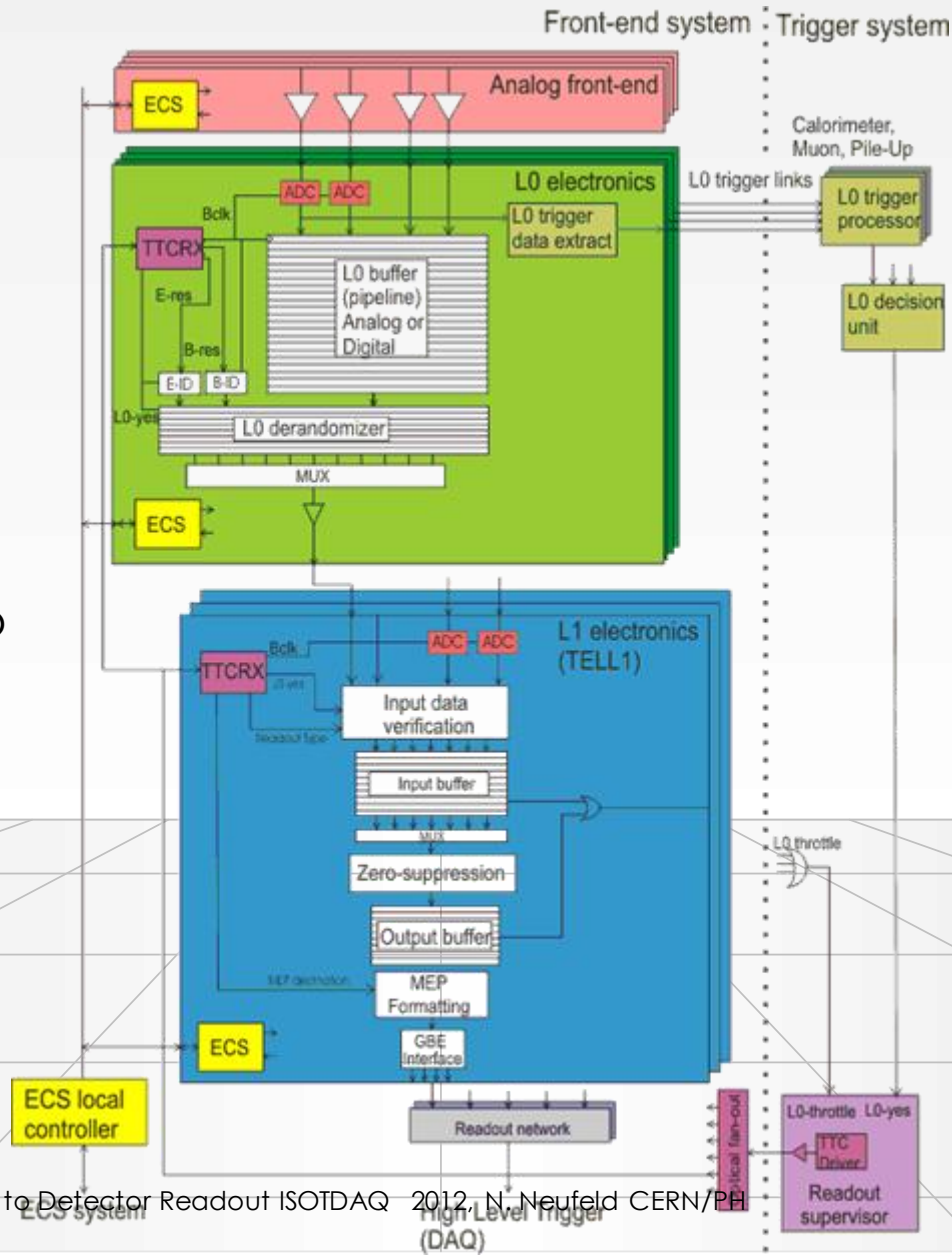

Complicated modules that are only half made when the hardware is there: FPGA firmware (from HDL), DSP code, on-board CPU software, etc.

Readout Architecture (LHCb)

FEE = Front End Electronics

Example from LHCb

Summary

- Detector read-out is mostly about sophisticated (analog) electronics
- Front-end electronics must fit the detector (noise, sensitivity) and the overall read-out architecture (trigger)
- Often there is a trade-off between cost and complexity in the front-end electronics and the subsequent dAQ
- This lecture is (hardly) the beginning...

More stuff

Transistors

- Exemple: bi-polar transistor of the NPN type
- C collector, E emitter, B Base
- EB diode is in forward bias: holes flow towards np boundary and into n region
- BC diode is in reverse bias: electrons flow AWAY from pn boundary
- p layer must be thinner than diffusion length of electrons so that they can go through from E to N without much recombination

from Wikipedia

Multilevel triggering

- First level triggering.
 - Hardwired trigger system to make trigger decision with short latency.
 - Constant latency buffers in the front-ends
- Second level triggering in DAQ interface
 - Processor based (standard CPU's or dedicated custom/DSP/FPGA processing)
 - FIFO buffers with each event getting accept/reject in sequential order
 - Circular buffer using event ID to extracted accepted events
 - Non accepted events stays and gets overwritten by new events
- High level triggering in the DAQ systems made with farms of CPU's: hundreds – thousands. (separate lectures on this)

ADC architectures

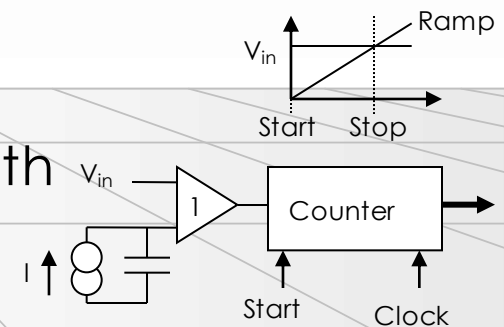

- Flash

- A discriminator for each of the 2^n codes
- New sample every clock cycle
- Fast, large, lots of power, limited to ~ 8 bits
- Can be split into two sub-ranging Flash $2 \times 2^{n/2}$ discriminators: e.g. 16 instead of 256 plus DAC
 - Needs sample and hold during the two stage conversion process

- Ramp

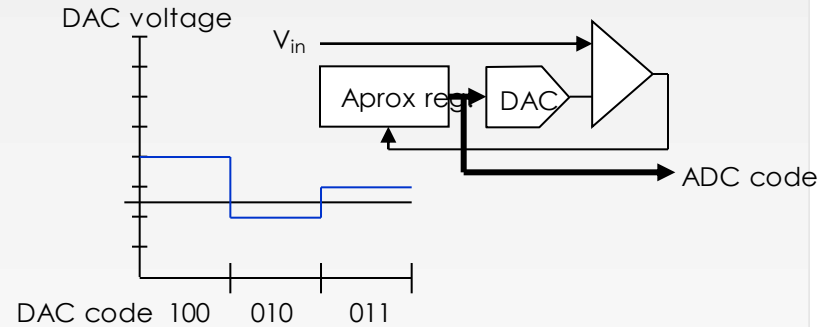

- Linear analog ramp and count clock cycles
- Takes 2^n clock cycles
- Slow, small, low power, can be made with large resolution

ADC architectures

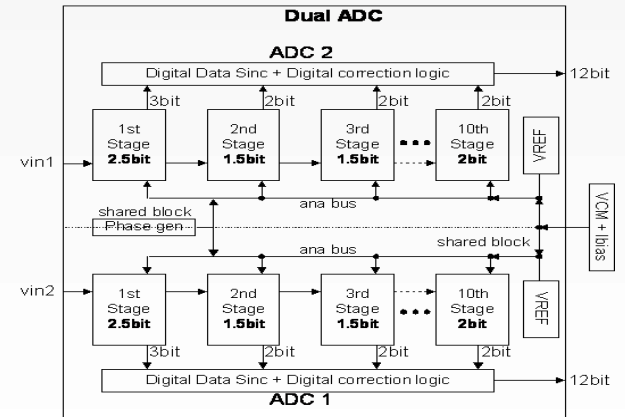

- Successive approximation

- Binary search via a DAC and single discriminator
- Takes n clock cycles
- Relatively slow, small, low power, medium to large resolution

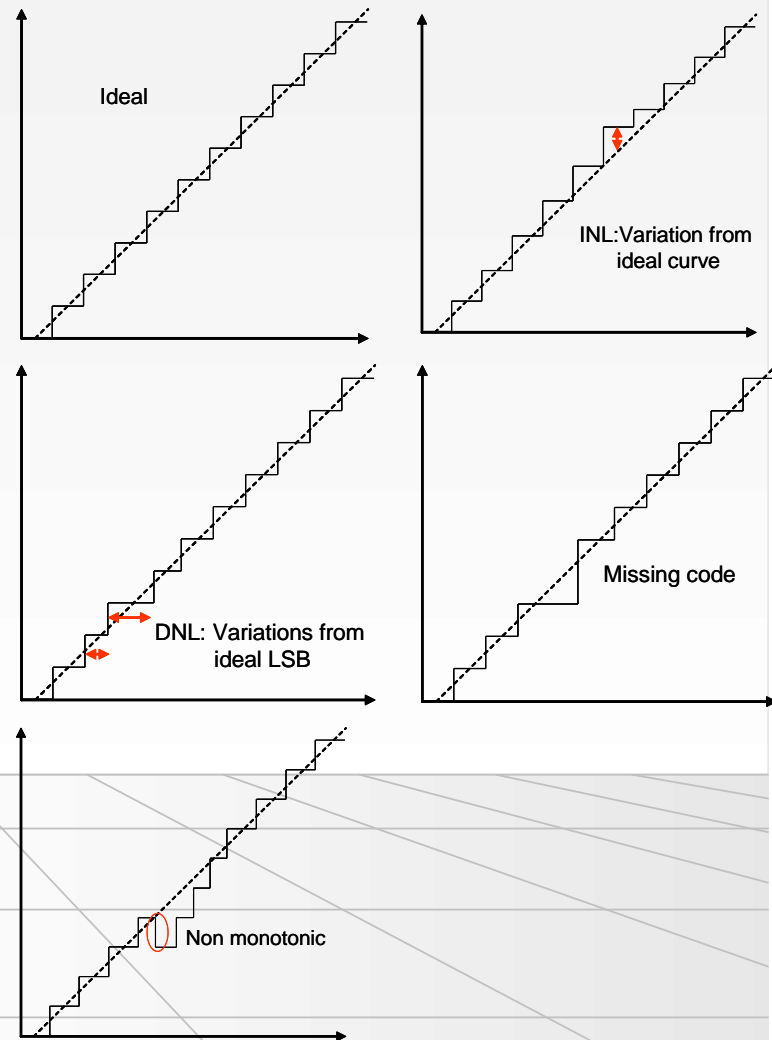

- Pipelined

- Determines "one bit" per clock cycle per stage
 - Extreme type of sub ranging flask
- n stages
- In principle 1 bit per stage but to handle imperfections each stage normally made with ~2bits and n*2bits mapped into n bits via digital mapping function that "auto corrects" imperfections
- Makes a conversion each clock cycle
- Has a latency of n clock cycles
 - Not a problem in our applications except for very fast triggering
- Now dominating ADC architecture in modern CMOS technologies and impressive improvements in the last 10 years: speed, bits, power, size

ADC imperfections

- Quantization (static)
 - Bin size: Least significant bit (LSB) = $V_{\max}/2^n$
 - Quantization error: RMS error/resolution: $\text{LSB}/\sqrt{12}$
- Integral non linearity (INL): Deviation from ideal conversion curve (static)
 - Max: Maximum deviation from ideal
 - RMS: Root mean square of deviations from ideal curve
- Differential non linearity (DNL): Deviation of quantization steps (static)
 - Min: Minimum value of quantization step
 - Max: Maximum value of quantization step
 - RMS: Root mean square of deviations from ideal quantization step
- Missing codes (static)
 - Some binary codes never present in digitized output
- Monotonic (static)
 - Non monotonic conversion can be quite unfortunate in some applications. A given output code can correspond to several input values.

New problems

- Going from single sensors to building detector read-out of the circuits we have seen, brings up a host of new problems:
 - Power, Cooling
 - Crosstalk
 - Radiation (LHC)
- Some can be tackled by (yet) more sophisticated technologies

(Large) Systems

Radiation effects

- In modern experiments large amounts of electronics are located inside the detector where there may be a high level of radiation
 - This is the case for 3 of the 4 LHC experiments **1 Rad = 10 mGy**
 - Pixel detectors: 10 -100 Mrad
 - Trackers: ~10Mrad
 - Calorimeters: 0.1 – 1Mrad
 - Muon detectors: ~10krad
 - Cavern: 1 – 10krad
- Normal commercial electronics will not survive within this environment
 - One of the reasons why all the on-detector electronics in the LHC experiment are custom made
- Special technologies and dedicated design approaches are needed to make electronics last in this unfriendly environment
- Radiation effects on electronics can be divided into three major effects
 - Total dose
 - Displacement damage
 - Single event upsets (for digital electronics only)

1 Rad = 10 mGy
1 Gy = 100 Rad

Total dose

- Generated charges from traversing particles gets trapped in insulators of the active devices and changes their properties
- For CMOS devices this happens in the thin gate oxide and can have a major impact on the function
 - Threshold shifts
 - Leakage current
- In deep submicron technologies (<math><0.25\mu\text{m}</math>) the trapped charges are removed by the electric field through the very thin gate oxide
 - Only limited threshold shifts
- The leakage currents caused by end effects of the (NMOS) can be cured by using enclosed transistors
 - For CMOS technologies below the 130nm generation the use of enclosed NMOS devices does not seem necessary. But other effects may show up
- No major effect on high speed bipolar technologies

Displacement damage

- Traversing hadrons provokes displacements of atoms in the silicon lattice.
- Bipolar devices relies extensively on effects in the silicon lattice.
 - Traps (band gap energy levels)
 - Increased carrier recombination in base
- Results in decreased gain of bipolar devices with a dependency on the dose rate.
- No significant effect on MOS devices
- Also seriously affects Lasers and PIN diodes used for optical links.

Single event upsets

- Deposition of sufficient charge can make a memory cell or a flip-flop change value
- As for SEL, sufficient charge can only be deposited via a nuclear interaction for traversing hadrons
- The sensitivity to this is expressed as an efficient cross section for this to occur
- This problem can be resolved at the circuit level or at the logic level
- Make memory element so large and slow that deposited charge not enough to flip bit
- Triple redundant (for registers)
- Hamming coding (for memories)

- Single error correction, Double error detection
- Example Hamming codes: 5 bit additional for 8 bit data

```

• ham[0] = d[1] $ d[2] $ d[3] $
  d[4];
ham[1] = d[1] $ d[5] $ d[6] $
  d[7];
ham[2] = d[2] $ d[3] $ d[5] $
  d[6] $ d[8];
ham[3] = d[2] $ d[4] $ d[5] $
  d[7] $ d[8];
ham[4] = d[1] $ d[3] $ d[4] $
  d[6] $ d[7] $ d[8];
$ = XOR
  
```

- Overhead decreasing for larger words
32bits only needs 7 hamming bits

Powering

- Delivering power to the front-end electronics highly embedded in the detectors has been seen to be a major challenge (underestimated).
- The related cooling and power cabling infrastructure is a serious problem of the inner trackers as any additional material seriously degrades the physics performance of the whole experiment.
- A large majority of the material in these detectors in LHC relates to the electronics, cooling and power and not to the silicon detector them selves (which was the initial belief)
- How to improve
 1. Lower power consumption
 2. Improve power distribution

Material budget in CMS Tracker

All electronics related

The problem as is

- Total power: ~500kw (to be supplied and cooled)
 - Trackers: ~ 60 kW
 - Calorimeters: ~ 300 kW
 - Muon: ~ 200 kW
 - Must for large scale detectors be delivered over 50m – 100m distance
- Direct supply of LV power from ~50m away
 - Big fat copper cables needed
 - Use aluminum cables for last 5-10m to reduce material budget
 - Power supply quality at end will not be good with varying power consumption (just simple resistive losses)
 - If power consumption constant then this could be OK
 - Use remote sense to compensate
 - This will have limited reaction speed
 - May even become unstable for certain load configurations
 - Power loss in cables will be significant for the voltages (2.5v) and currents needed: ~50% loss in cables (that needs to be cooled)
- Use of local linear regulators
 - Improves power quality at end load.
 - Adds additional power loss: 1 – 2 v head room needed for regulator
 - Increases power losses and total efficiency now only: ~25% (more cooling needed)

Use of DC-DC converters

- For high power consumers (e.g. calorimeter) the use of local DC-DC converters are inevitable.
- These must work in radiation and high magnetic fields
 - This is not exactly what switched mode DC-DC converters like
 - Magnetic coils and transformers saturated
 - Power devices do not at all like radiation: SEU -> single event burnout -> smoke -> disaster
- DC-DC converters for moderate radiation and moderate magnetic fields have been developed and used
 - Some worries about the actual reliability of these for long term
