
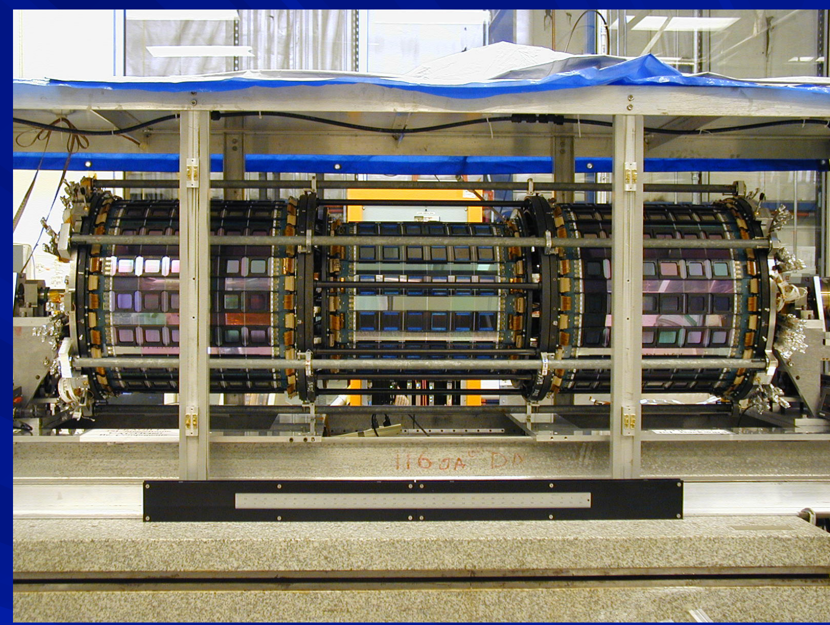
Detectors for Particle Physics

Semiconductor Detectors

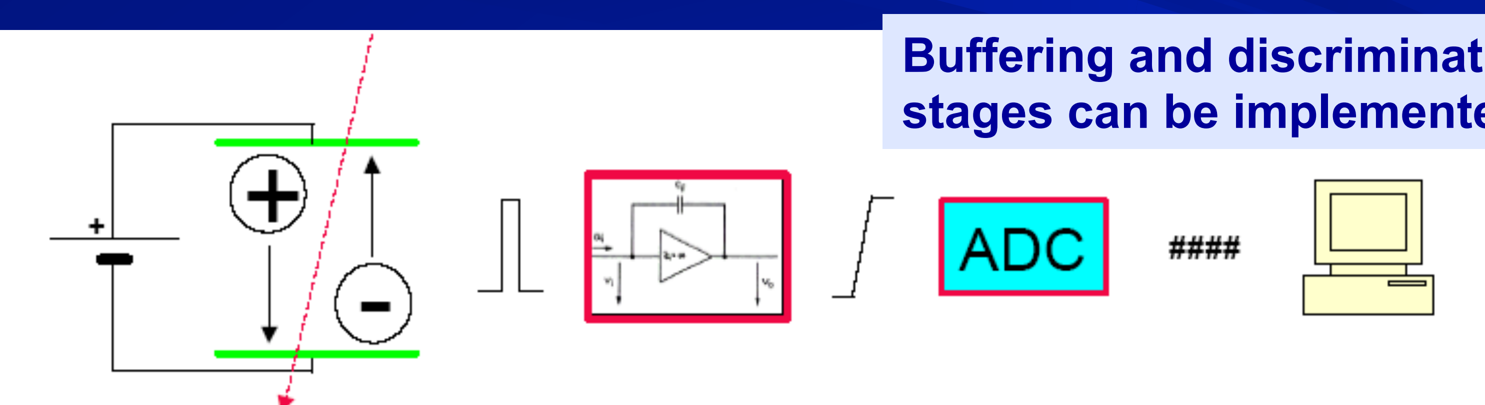
D. Bortoletto
Purdue University

Definition

- A solid state (silicon) detector is an ionization chamber
  - Sensitive volume with electric field
  - Energy deposited creates e-h pairs
  - Charge drifts under E field
  - Get integrated by ROC
  - Then digitized
  - And finally is read-out and stored

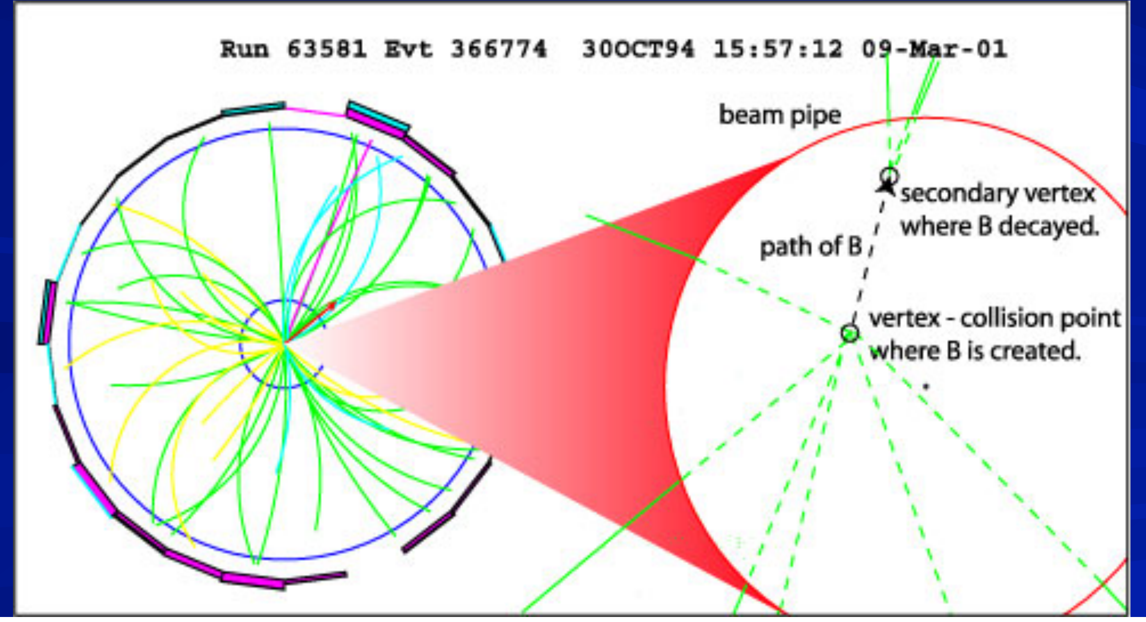


Buffering and discriminations stages can be implemented



Tracking and Vertex Detector

- Solid state detectors especially silicon offer high segmentation
- Determine position of primary interaction vertex and secondary decays



- Lifetime tags to identify B-hadrons (or tau leptons,...)
  - Impact parameter (IP)
  - Measurement of secondary vertex
- precision track reconstruction essential since $c\tau \approx 500\ \mu m$

A brief history of solid state detectors

- J. Kemmer 1979

NUCLEAR INSTRUMENTS AND METHODS 169 (1980) 499-502, © NORTH HOLLAND PUBLISHING CO

FABRICATION OF LOW NOISE SILICON RADIATION DETECTORS BY THE PLANAR PROCESS

J KEMMER

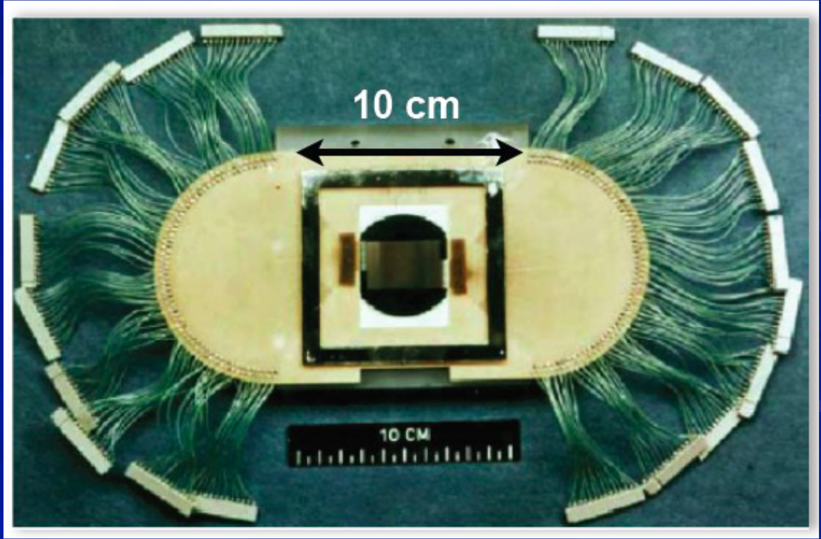
Fachbereich Physik der Technischen Universitat Munchen, 8046 Garching, Germany

Received 30 July 1979 and in revised form 22 October 1979

Dedicated to Prof Dr H -J Born on the occasion of his 70th birthday

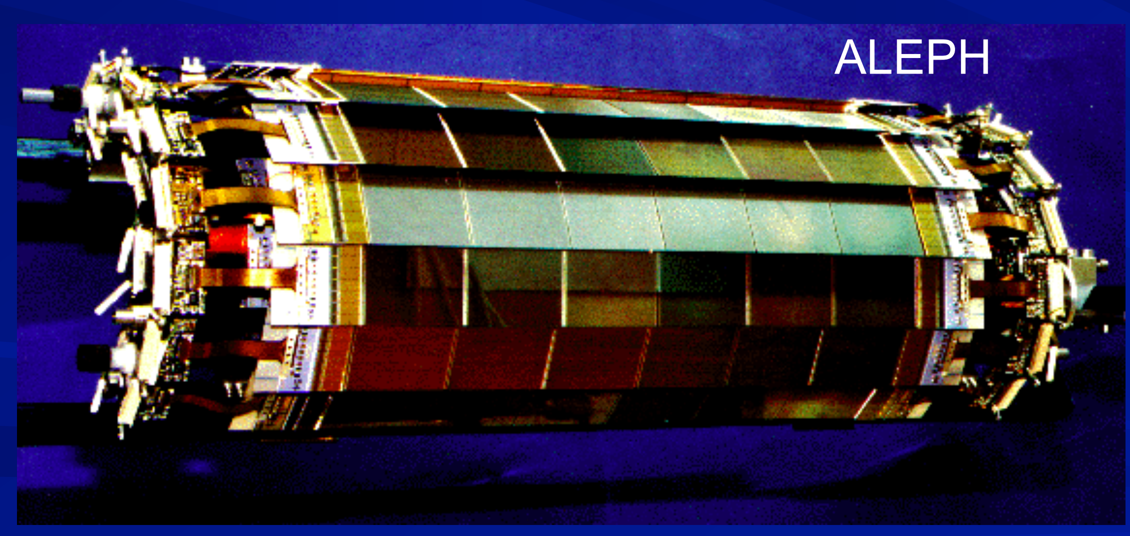
By applying the well known techniques of the planar process oxide passivation, photo engraving and ion implantation, Si pn-junction detectors were fabricated with leakage currents of less than 1 nA cm^{-2}/100 μm at room temperature Best values for the energy resolution were 10.0 keV for the 5.486 MeV alphas of ^{241}Am at 22°C using 5×5 mm^2 detector chips

- NA11 at CERN
  - First use of a position-sensitive silicon detector in HEP experiment
  - Measurement of charm quark lifetimes
  - 1200 diode strips on 24x 36 mm^2
  - 250-500 μm thick bulk material
  - 4.5 μm resolution



LEP and SLAC

- **LEP and SLAC**
  - Readout ASICs at end of ladders
  - Minimize mass inside tracking volume
  - Minimize mass between interaction point and detectors
  - Minimize the distance between interaction point and the detectors
- Enabled measurement of b-quark lifetimes and b-tagging



- 2 silicon layers, 40cm long, inner radius 6.3cm, outer radius 11cm
- 300 μm silicon wafers giving thickness of only $0.015X_0$
- S/N(r-ϕ) = 28:1
- S/N(z)= 17:1
- r-ϕ= 12 μm; z = 14μm

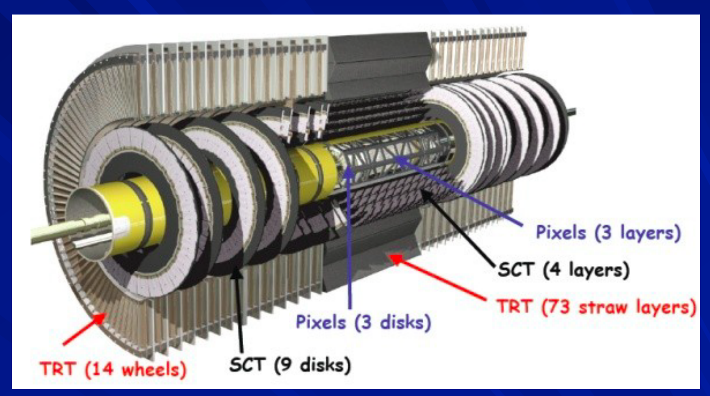
CDF & D0

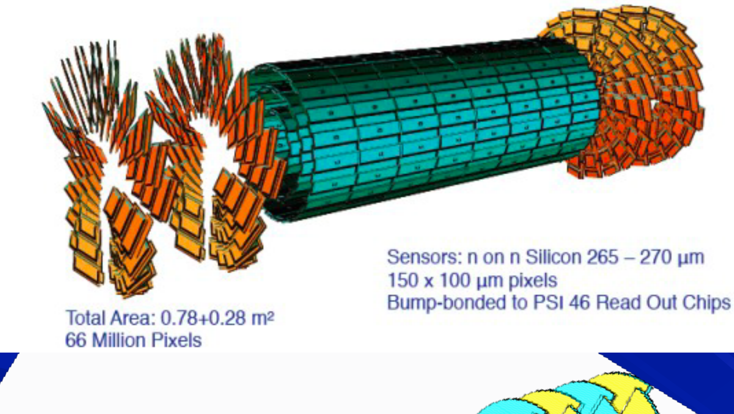
- CDF pioneered the silicon vertex detector in the hadron collider environment and pioneered the silicon vertex trigger separating *b*-hadrons
- Emphasis shifted to tracking + vertexing allowing precision measurements in very complex environment
- Cover large area with many silicon layers
- Detector modules including ASIC's and services INSIDE the tracking volume

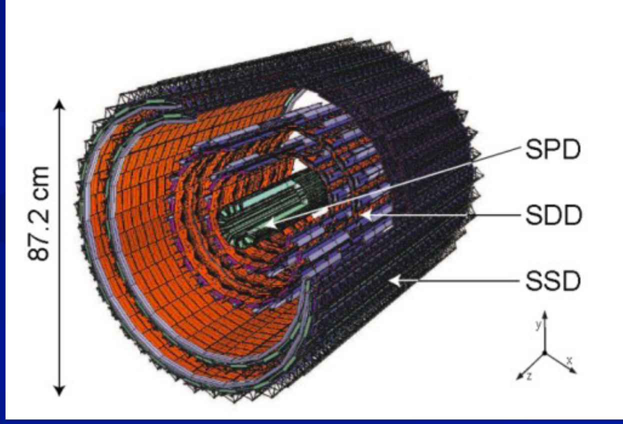
CDF's first Silicon Vertex Detector at the Smithsonian Museum, Washington

The LHC silicon detectors

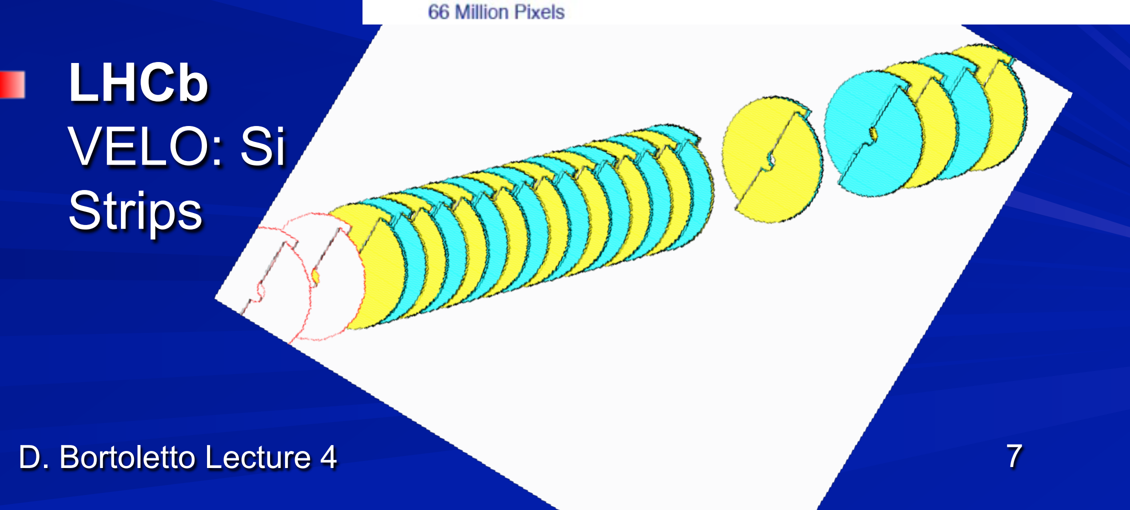
- **ATLAS** Strips: 61 m^2 of silicon, 4088 modules, 6x106 channels Pixels: 1744 modules, 80 x 10^6 channels
- **CMS** the world largest silicon tracker 200 m^2 of strip sensors (single sided) 11 x 106 readout channels ~1m^2 of pixel sensors, 60x10^6 channels
- **ALICE** Pixel sensors Drift detectors Double sided strip detectors







- **LHCb** VELO: Si Strips



The LHC detectors

From LEP to the LHC

Comparison solid state versus gas

Ionization chamber medium could be gas, liquid, or solid

- **Gas ⇒ electron and ion pairs; Semiconductor ⇒electron and hole pairs**

	Gas	Solid
Density	Low	High
Atomic number (Z)	Low	Moderate (Z=14)
Ionization Energy (ε_I)	Moderate (≈ 30 eV)	Low (≈3.6 eV)
Signal Speed	Moderate (10ns-10μs)	Fast (<20 ns)

Solid State Detectors

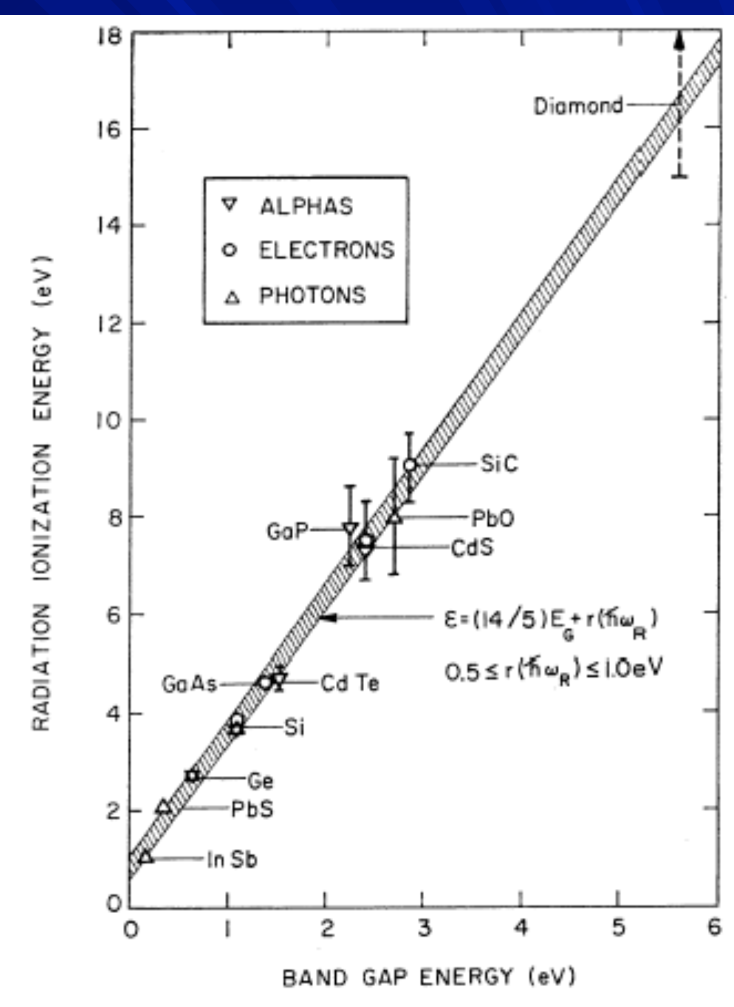
- Energy (E) to create e-h pairs 10 times smaller than gas ionization ⇒ increase charge⇒ good E resolution

$$\frac{\Delta E}{E} \propto \frac{1}{\sqrt{N}} \propto \frac{1}{\sqrt{E/\varepsilon_I}} \propto \sqrt{\varepsilon_I}$$

- Greater density
  - Reduced range of secondary electrons ⇒ excellent spatial resolution
  - Average E_{loss} ≈390eV/ μm ≈108 e-h/ μm (charge collected is a function of thickness d but no multiplication)
- To minimize multiple scattering d should be small, 300 μm ≈32,000 e-h pairs yields good S/N

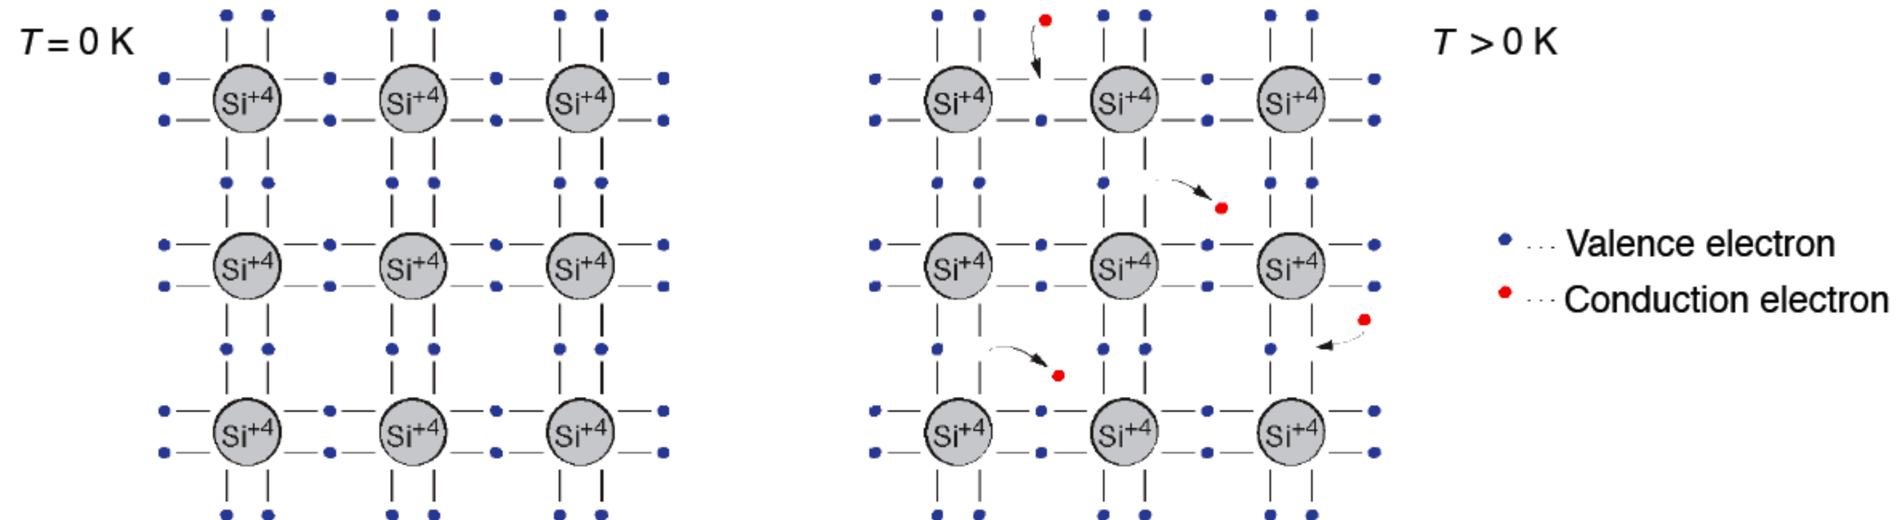
Silicon Properties

- Excellent detector material
  - Low ionization energy (good signal). The band gap is 1.12 eV, but it takes 3.6 eV to ionize an atom. The remaining energy goes to phonon excitations (heat).
  - Long mean free path (good charge collection efficiency)
  - High mobility (fast charge collection)
  - Low Z (Z=14 low multiple scattering)
- Oxide (SiO_2) has excellent electrical properties
- Good mechanical properties
  - Easily patterned to small dimensions
  - Can be operated in air and at room temperature (many SSD require cooling)
- Industrial experience and commercial applications
- Crystalline ⇒ radiation damage



Bond Model

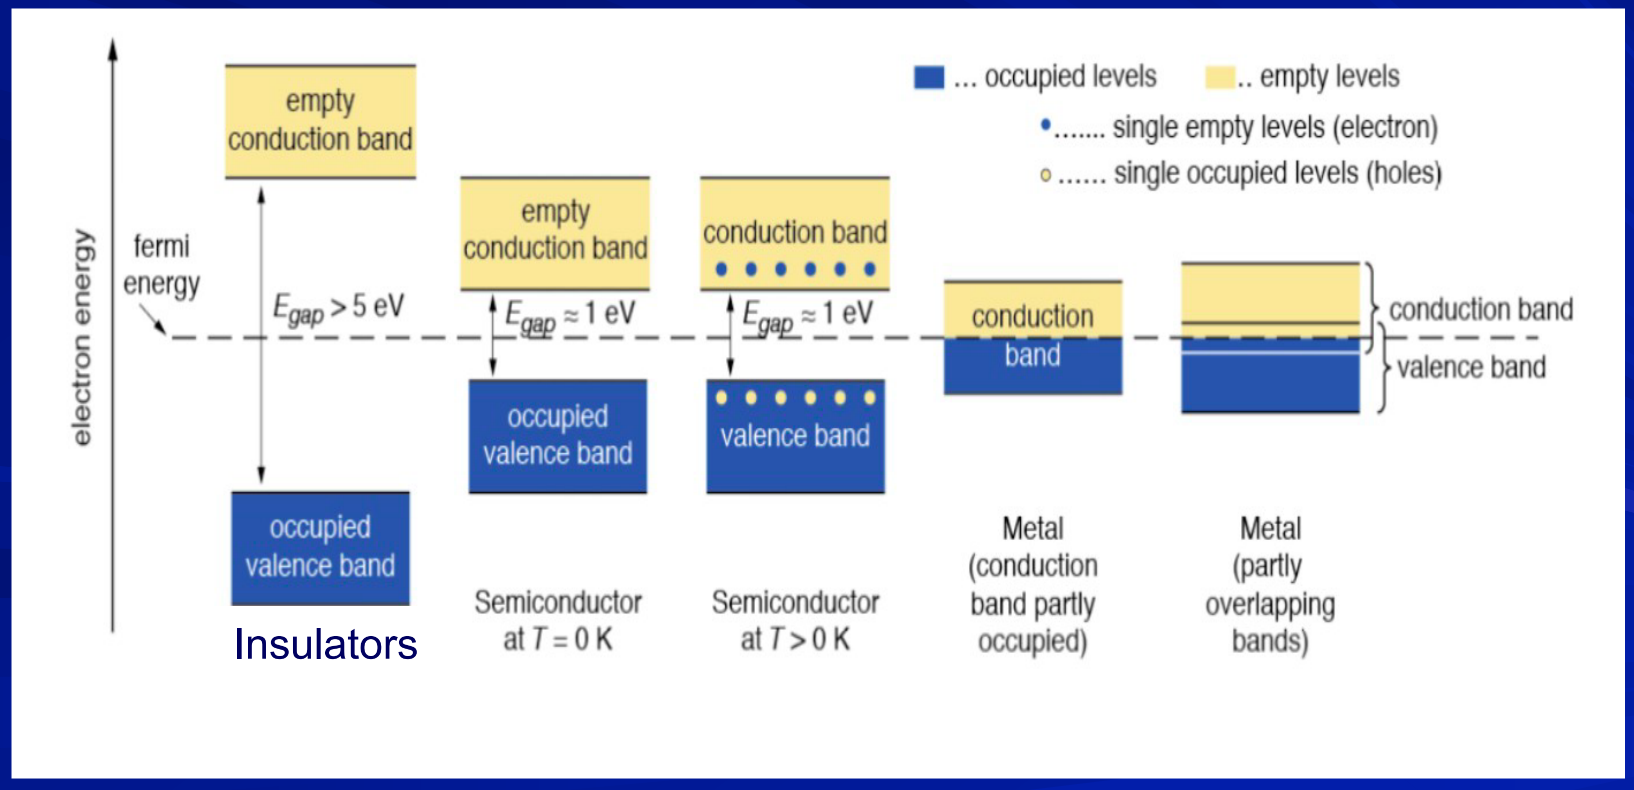
- Example of column IV elemental semiconductor:



- Each atom has 4 closest neighbors, the 4 electrons in the outer shell are shared and form **covalent bonds**.
  - At low temperature all electrons are bound
  - At higher temperature thermal vibrations break some of the bonds
  - free e^- cause conductivity (electron conduction)
  - The remaining open bonds attract other e^- ➔The “holes” change position (hole conduction)

Energy bands

- Electrons in isolated atoms have discrete energy levels.
- In a solid the levels merge to energy bands.
  - In **metals** the conduction and the valence band **overlap**
  - In insulators and semiconductors levels are **separated** by an energy gap (**band gap**).



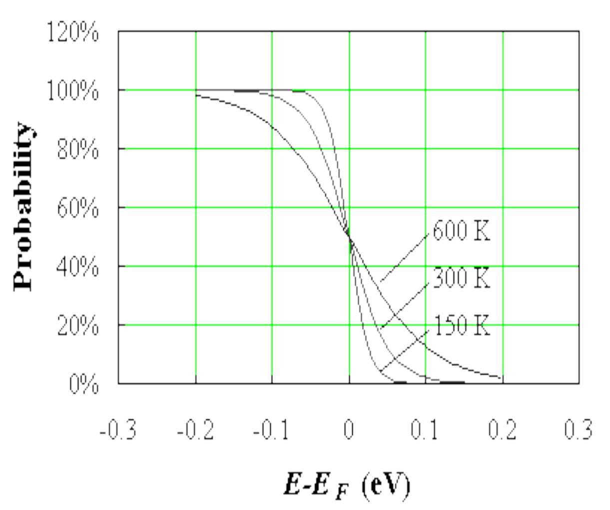
Intrinsic Carrier concentration

- Small band gap in semiconductors ➔ electrons already occupy the conduction band at room temperature.
- Electrons in the conduction band may recombine with holes.
- **Thermal equilibrium** is reached between **excitation** and **recombination when the** charge carrier concentration $n_e = n_h = n_i$= intrinsic carrier concentration:

$$n_i = \sqrt{N_C N_V} \cdot \exp\left(-\frac{E_g}{2kT}\right) \approx T^{3/2} \exp\left(-\frac{E_g}{2kT}\right)$$

Ultrapure silicon n_i=**1.45·10^{10} cm^{-3}**. There are 10^{22} Atoms/cm^3 ➔ 1/10^{12} silicon atoms is ionized.

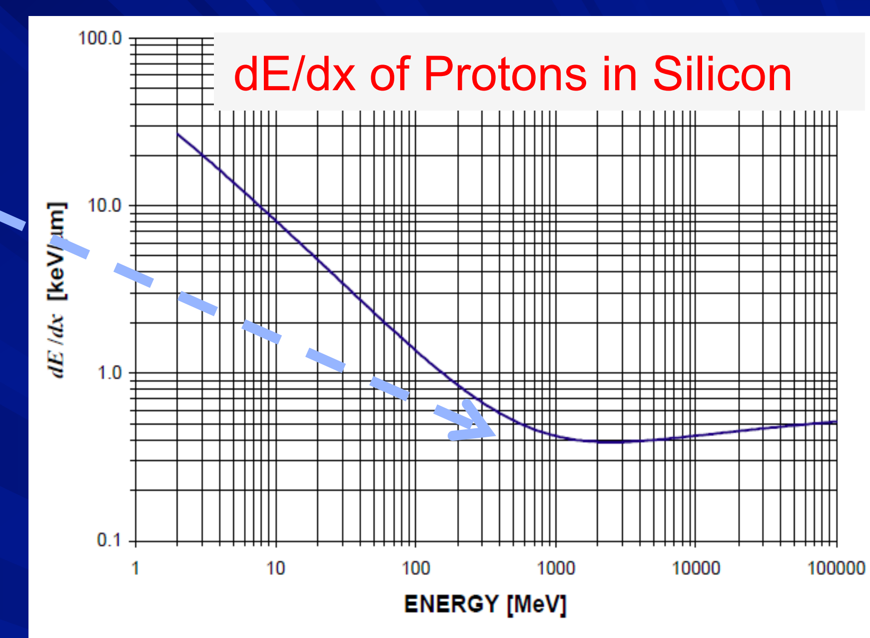
- The probability that an energy state is occupied by an e^- is given by the Fermi-Dirac distribution Where E_F is at mid-gap for intrinsic silicon



$$f = \frac{1}{1 + e^{\frac{E - E_F}{kT}}}$$

Principle of operation

- Mean ionization energy I_0 = **3.62 eV**
- Mean energy loss per flight path of a mip ***dE/dx* = 3.87 MeV/cm**

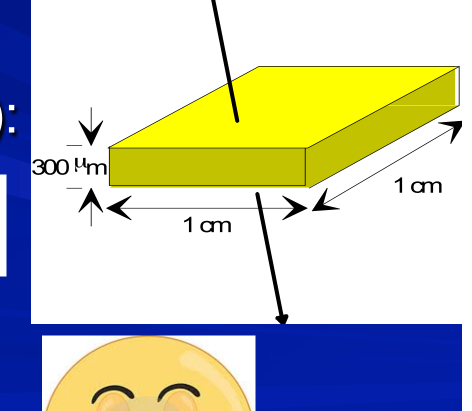


- Assuming a detector of thickness *d* = 300 µm and an area of *A* = 1 cm².
- **MIP signal is**

$$\frac{(dE/dx)d}{I_0} = \frac{3.87\cdot 10^6 eV/cm \cdot 0.03cm}{3.63eV} \cong 3.2\cdot 10^4 \text{e-h pairs}$$

- **Intrinsic charge carrier in the same volume** (*T* = 300 K):

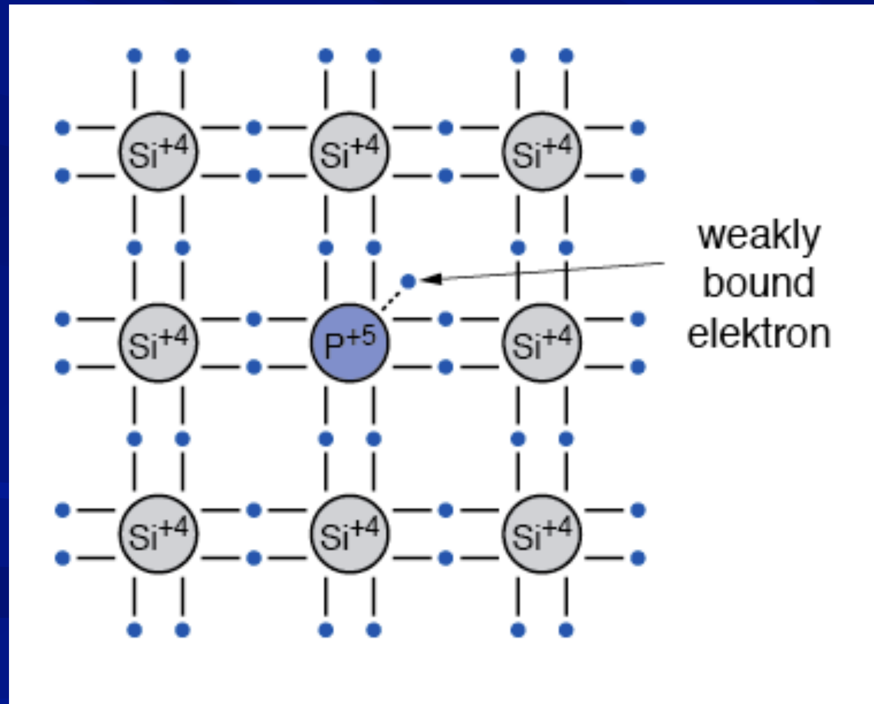
$$n_i dA = 1.45\cdot 10^{10} cm^{-3}\cdot 0.03cm\cdot 1cm^2 \cong 4.35\cdot 10^8 \text{e-h pairs}$$

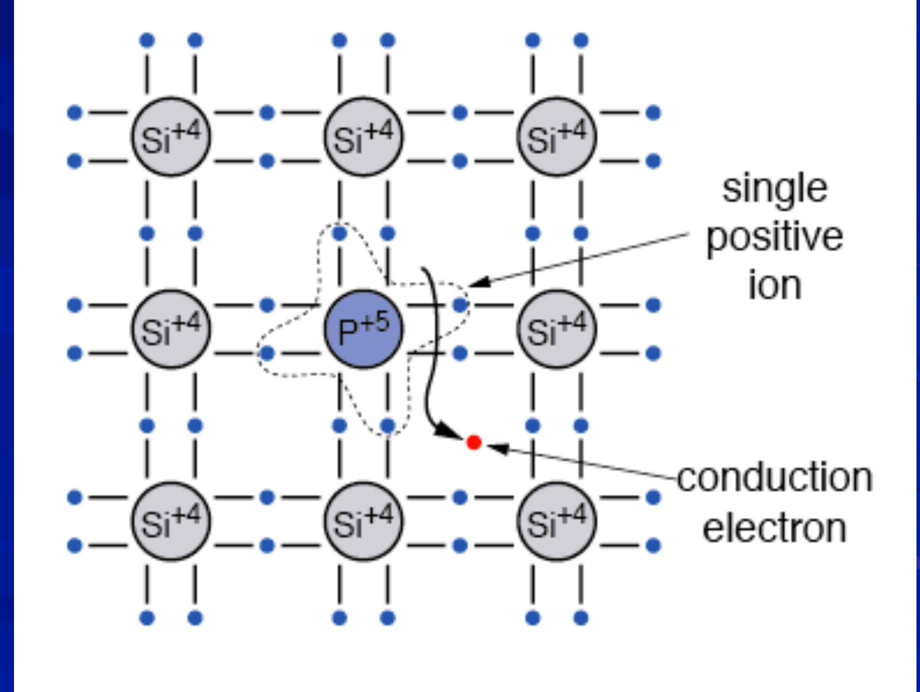


- The number of thermal created e–h-pairs (noise) is four orders of magnitude larger than the signal
- We need to deplete the free charge carriers

n-type silicon

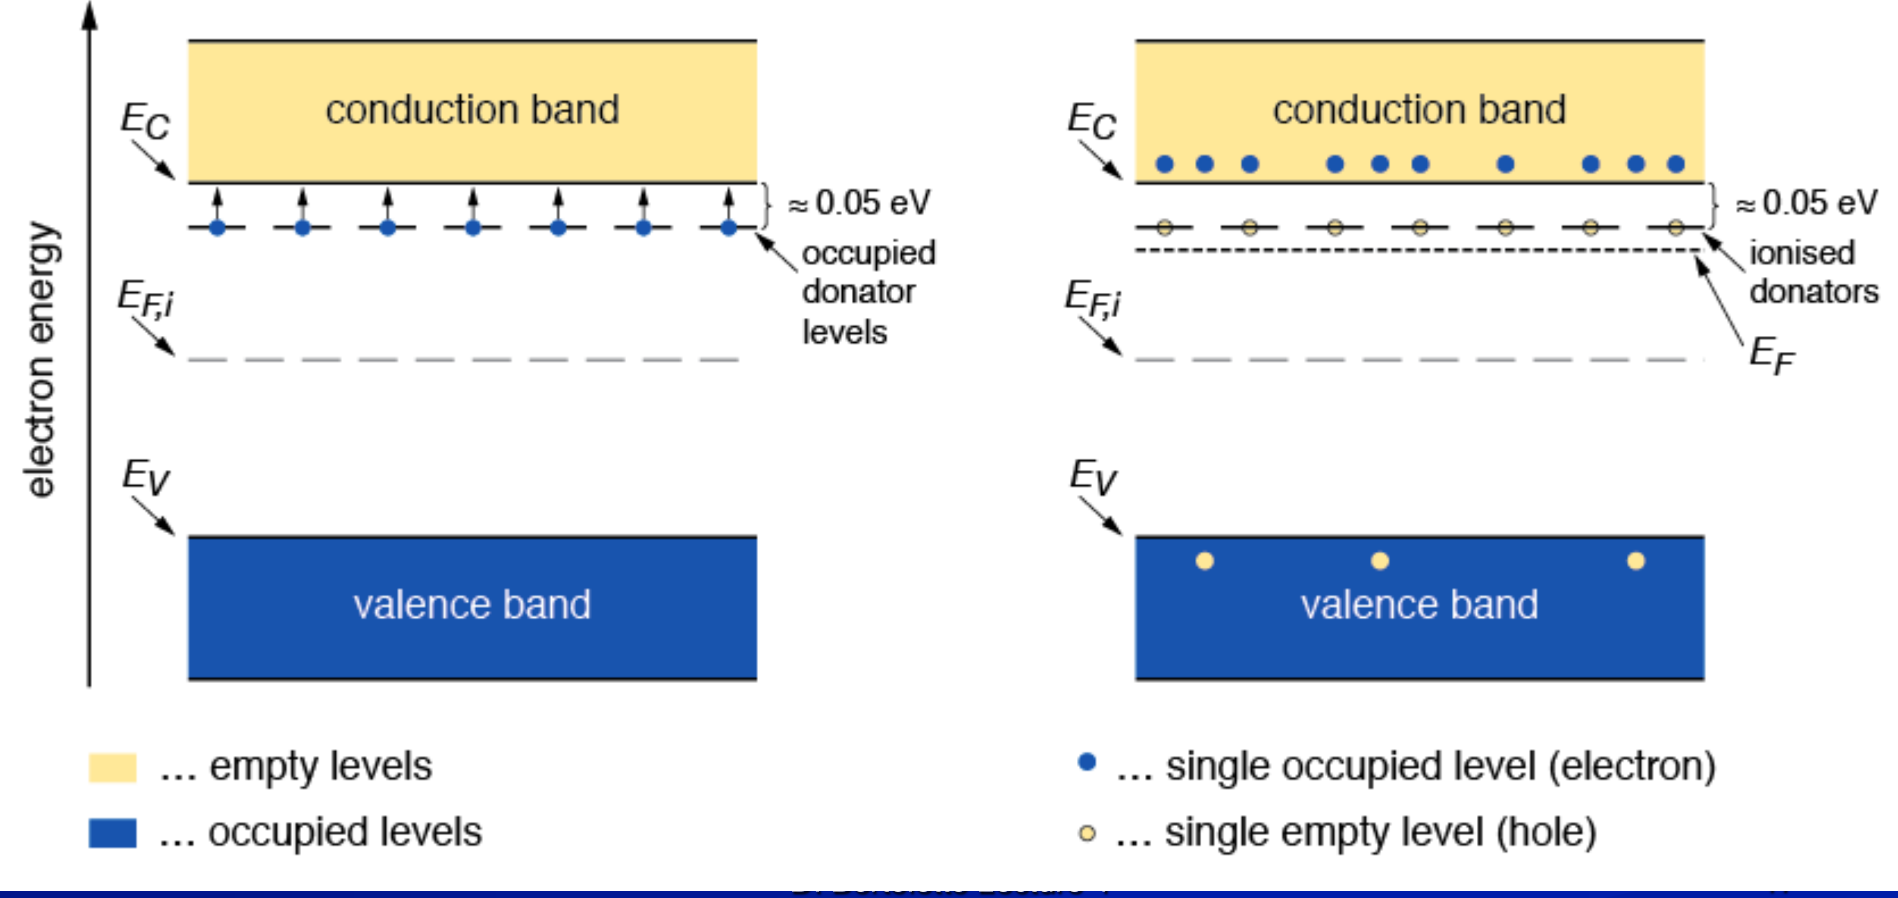
- Doping with an element V atom (e.g. P, As, Sb). The 5th valence electron is weakly bound.
- The doping atom is called **donor.**
- Negatively charged electrons are the majority carriers and the space charge is positive.





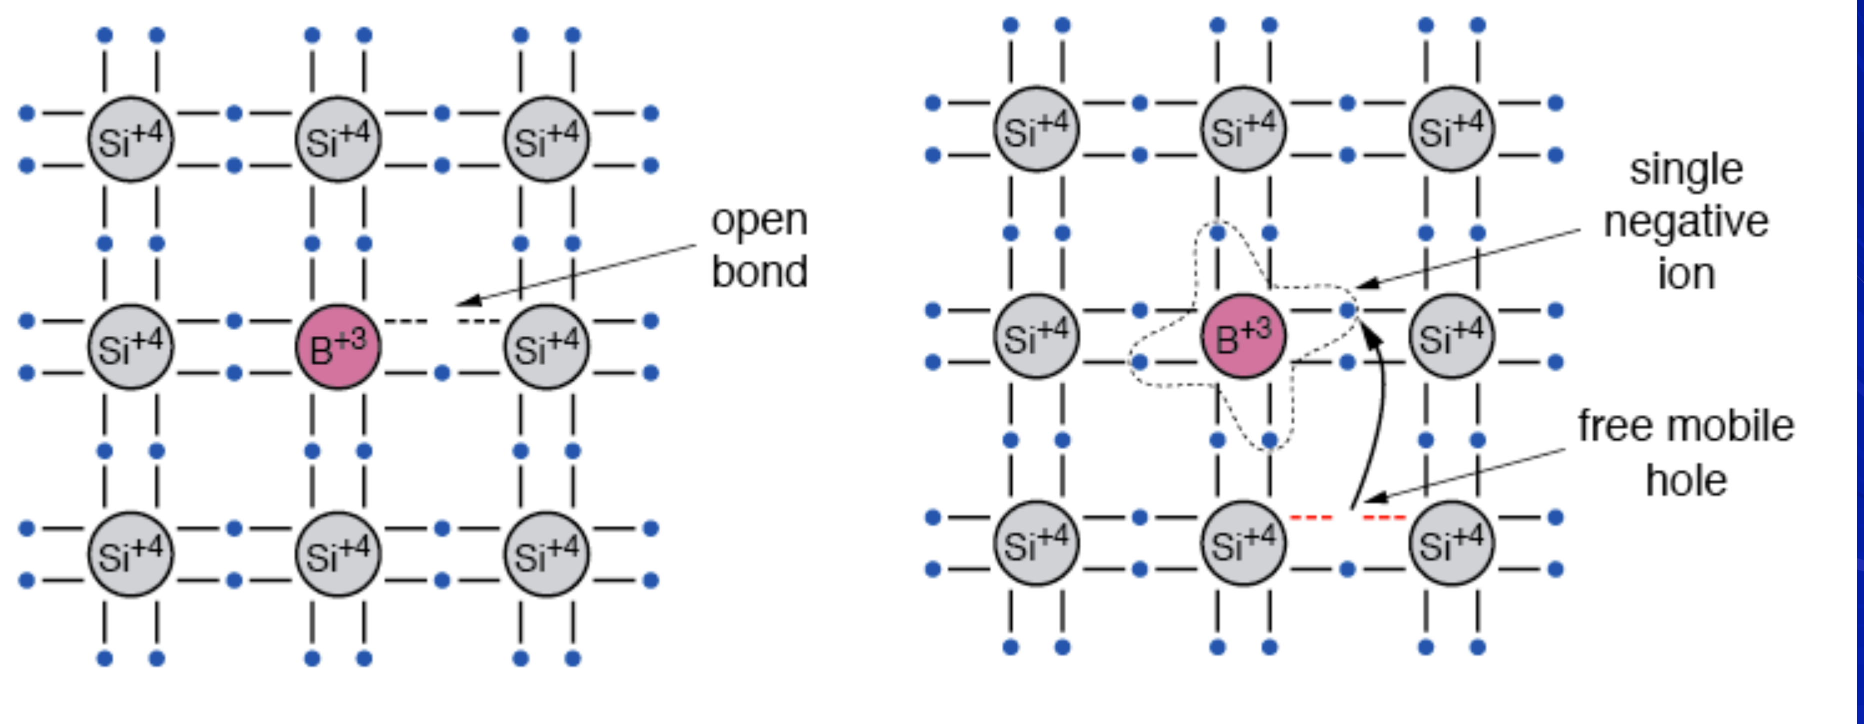
n-type silicon

- The energy level of the donor is just below the edge of the conduction band. At room temperature most electrons are raised to the conduction band.
- The Fermi level E_F moves up.



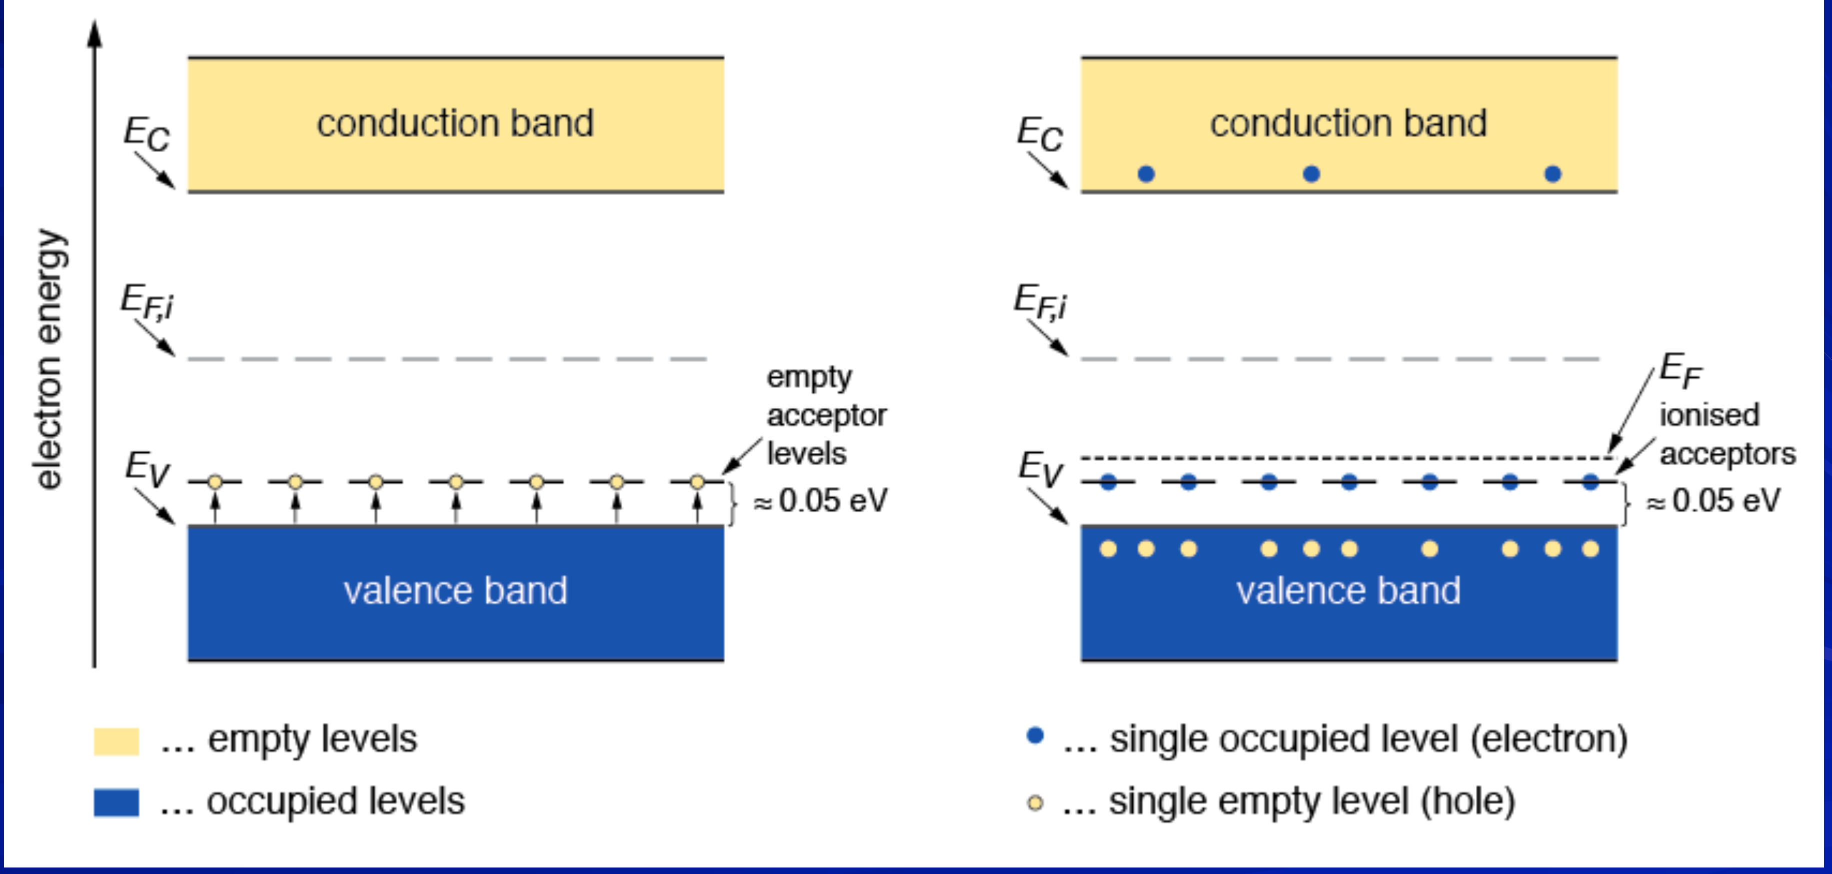
p-type silicon

- Doping with an element III atom (e.g. B, Al, Ga, In). One valence bond remains open. This open bond attracts electrons from the neighbor atoms.
- The doping atom is called **acceptor**.
- Positively charged holes are the majority carriers and the space charge is negative.



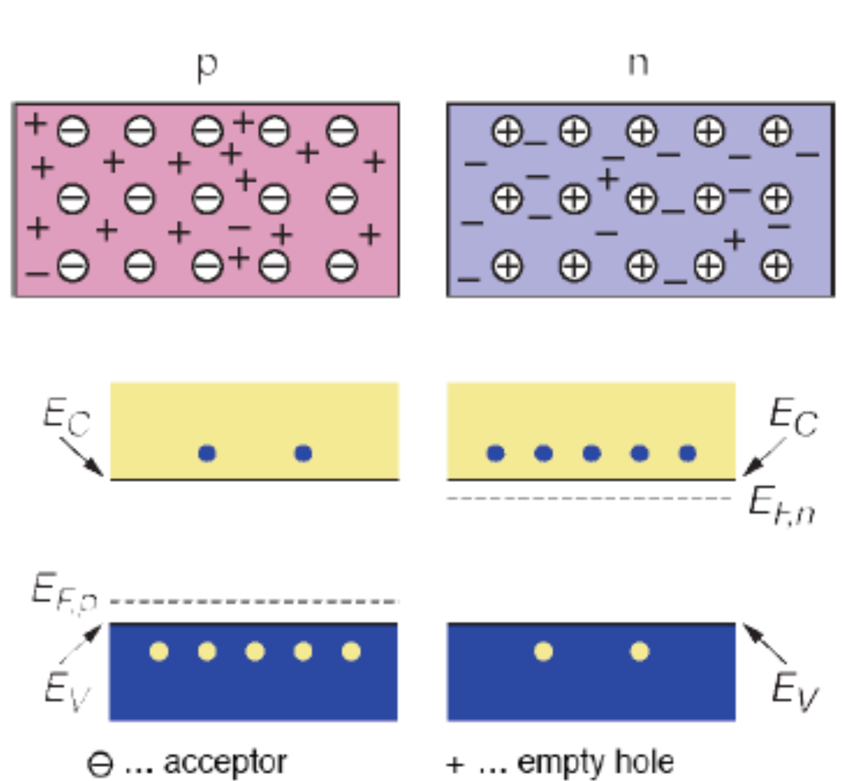
p type silicon

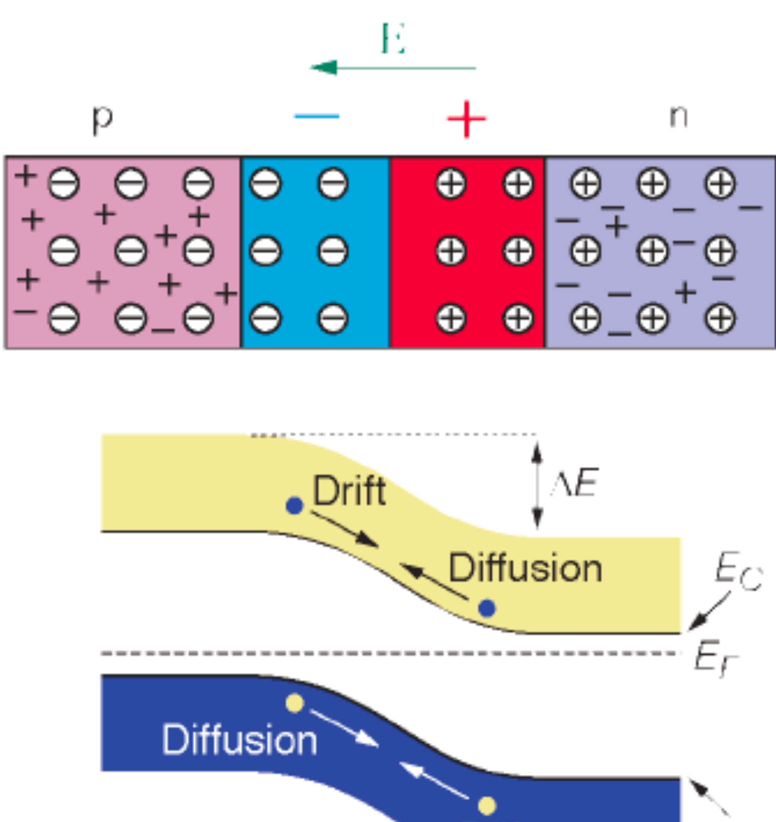
- The energy level of the acceptor is just above the edge of the valence band. At room temperature most levels are occupied by electrons leaving holes in the valence band.
- The Fermi level E_F moves down.



The p-n junctions

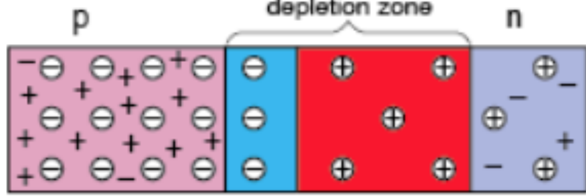
- At the interface of n-type and p-type silicon the difference in the Fermi levels cause diffusion of excessive carries until thermal equilibrium is reached and the Fermi level is equal.
- The remaining ions create a **space charge region** and an electric field stopping further diffusion ➔the depletion zone.





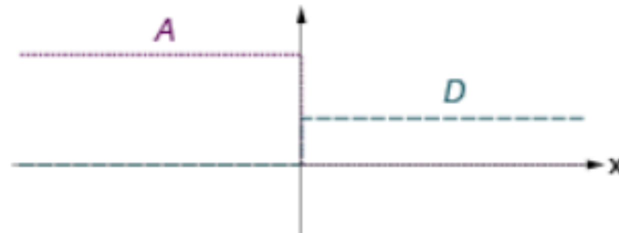
The pn-junction

pn junction scheme

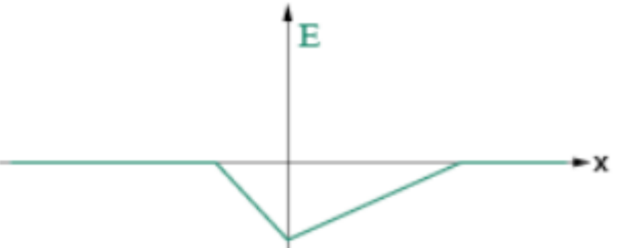


concentration of free charge carriers

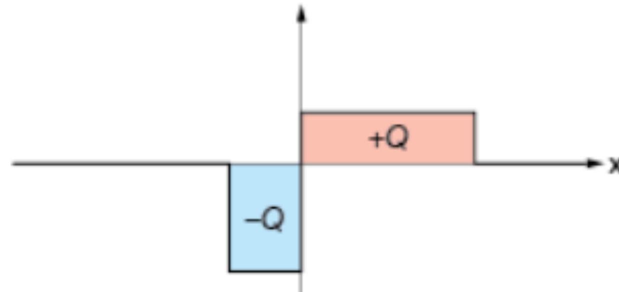
acceptor and donator concentration



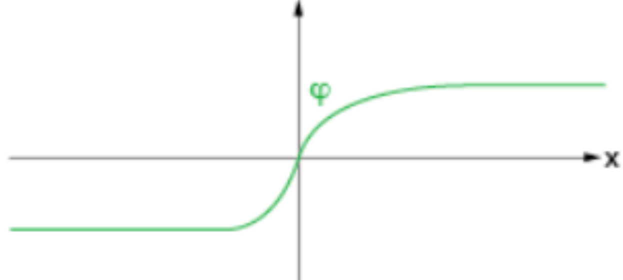
electric field



space charge density



electric potential



⊖ ... acceptor

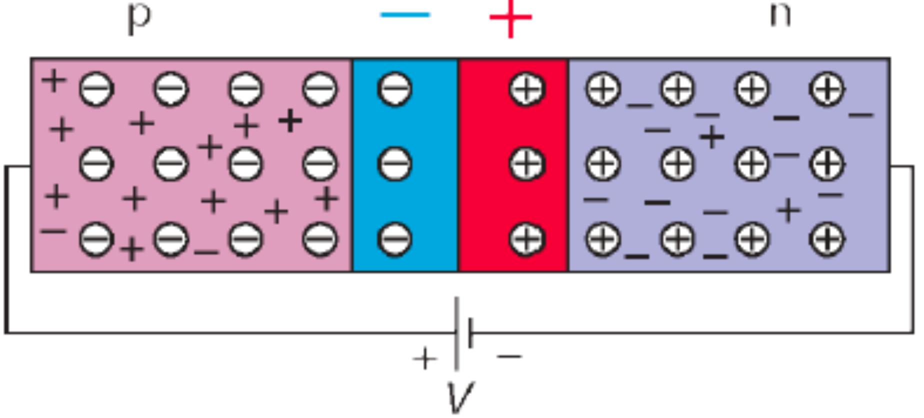
⊕ ... donator

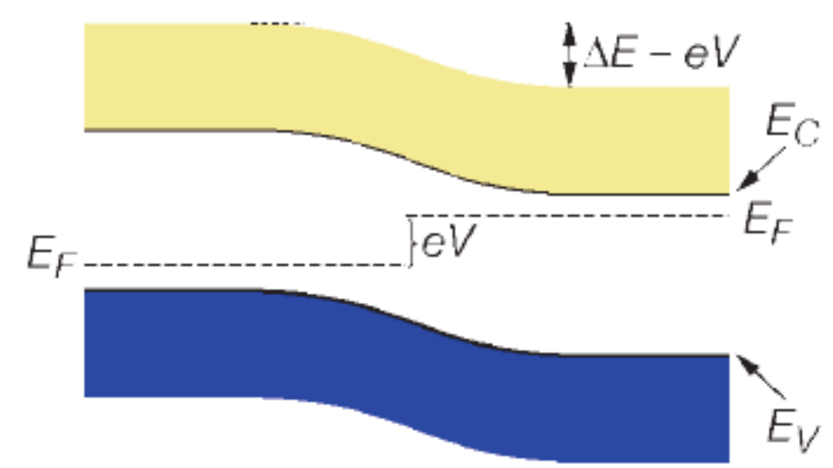
\+ ... empty hole

− ... conduction electron

P-n junction: Forward bias

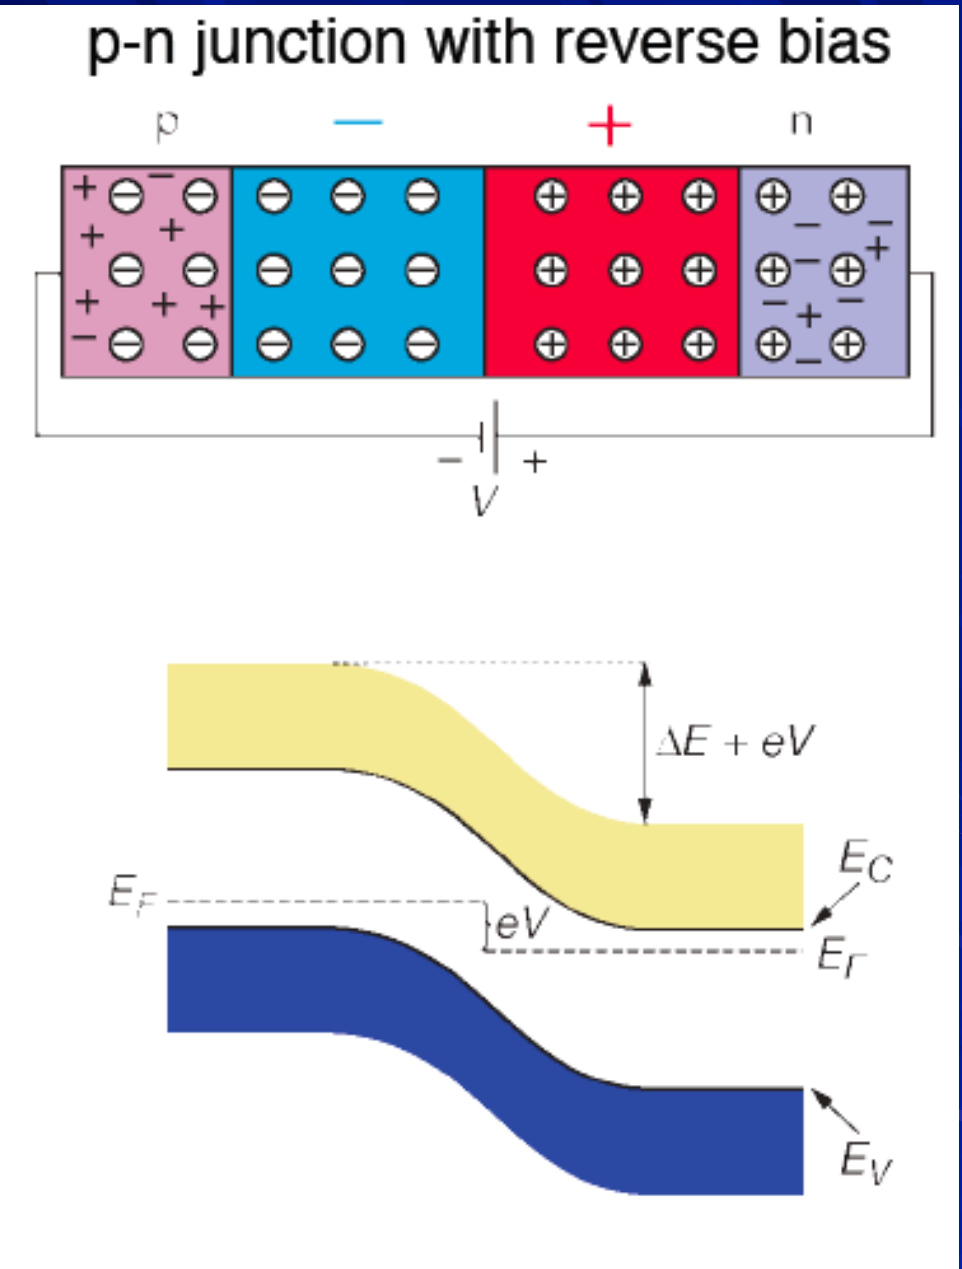
- Apply an external voltage V with (-) to n-side and (+) to p-side
  - The **depletion zone becomes narrower** (forward biasing)
- **Consequences:**
  - The potential barrier becomes smaller by eV
  - Diffusion across the junction becomes easier
  - The current across the junction increases significantly.





pn-junction with reverse bias

- Apply an external voltage V with (-) to p and the (-) to n side. e- and holes are pulled out of the depletion zone.
  - The **depletion zone becomes larger** (reverse biasing).
- **Consequences:**
  - The potential barrier becomes higher by *eV*
  - Diffusion across the junction is suppressed.
  - The current across the junction is very small (“leakage current”)
- This is the way we operate semiconductor detectors



Width of the depletion zone

- Solve Poisson eq. using conservation of charge $N_A d_p = N_D d_n$
- Effective doping concentration in typical silicon detector with p+-n junction
  - $N_a = 10^{15}\ cm^{-3}$ in p+ region
  - $N_d = 10^{12}\ cm^{-3}$ in n bulk.
- Without external voltage:
  - $W_p = 0.02\ \mu m$
  - $W_n = 23\ \mu m$
- Applying a reverse bias voltage of 100 V:
  - $W_p = 0.4\ \mu m$
  - $W_n = 363\ \mu m$
- Width of depletion zone in n bulk:

$$W_p = \sqrt{\frac{2\varepsilon|V|}{q}\frac{1}{N_A(1+N_A/N_D)}}$$

$$W_n = \sqrt{\frac{2\varepsilon|V|}{q}\frac{1}{N_D(1+N_D/N_A)}}$$

p+ $N_a \approx 10^{15}\ cm^{-3}$

n

$N_d \approx 10^{12}\ cm^{-3}$

$$W = \sqrt{\frac{2\varepsilon V_{bias}}{q}\frac{1}{N_D}} \quad if \;\; N_A >> N_D$$

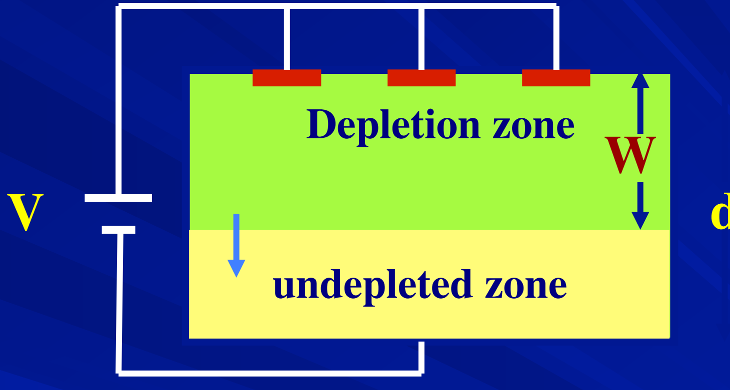
$$W \approx \sqrt{2\varepsilon_0\varepsilon_r \mu\rho|V|} \quad with \quad \rho = \frac{1}{e\mu N_{eff}}$$

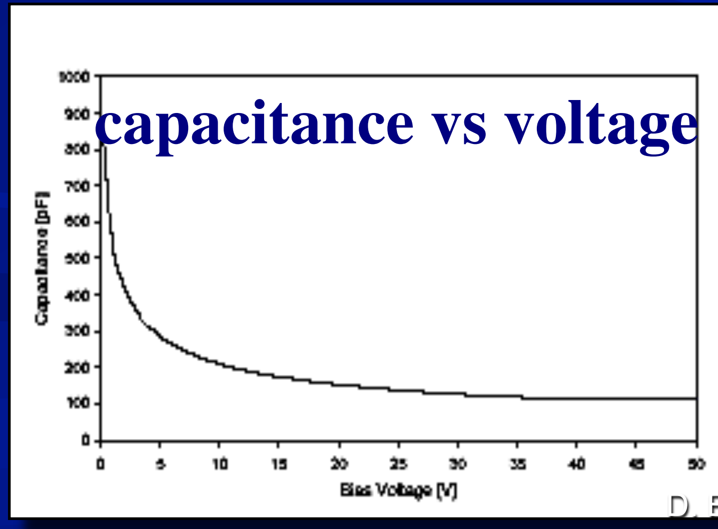
The voltage needed to completely deplete a device of thickness d is called the depletion voltage V_d

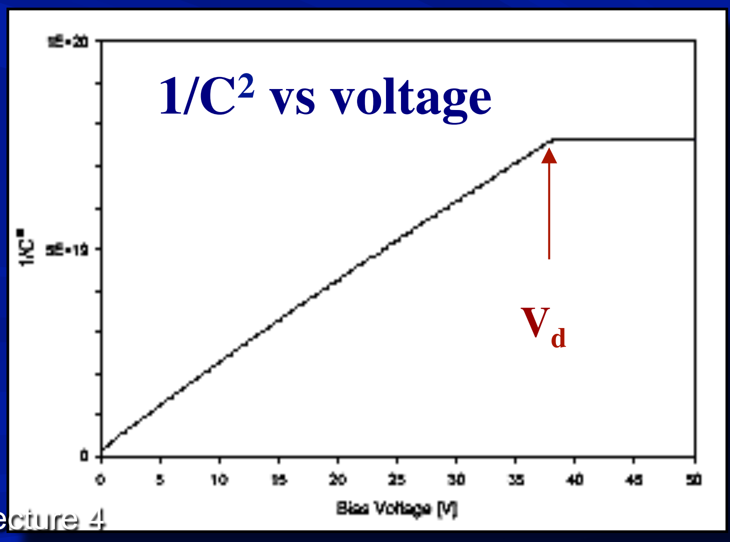
Depletion Zone & Capacitance

- The depletion voltage can be determined by measuring the capacitance versus reverse bias voltage. The capacitance is simply the parallel plate capacity of the depletion zone.

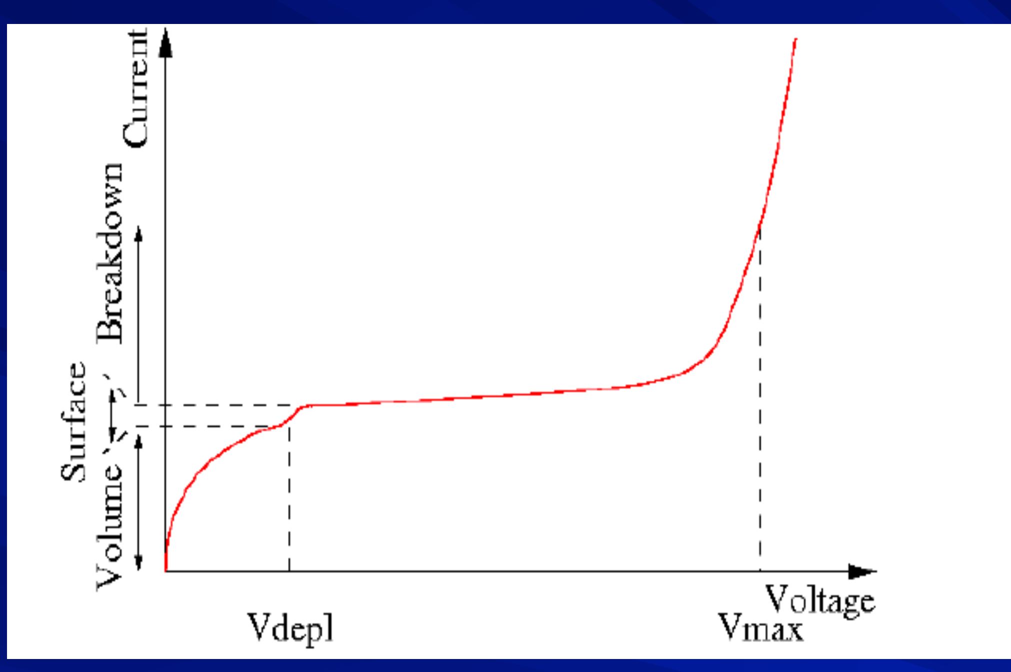
$$C = \frac{\varepsilon A}{d} = A\sqrt{\frac{\varepsilon}{2\rho\mu V_b}}$$







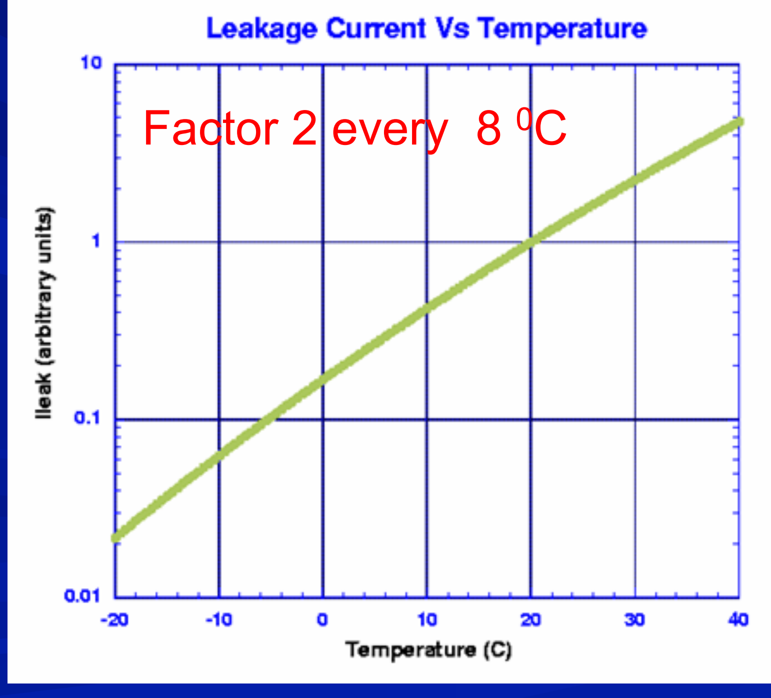
Leakage current



I_{leak} sensitive to process quality

Diffusion current

- charge generated in the undepleted zone adjacent to the depletion zone which diffuse into the depletion zone



Generation current

- From thermal generation in the depletion region
- Reduced by using pure and defect free material with high carrier lifetime
- Keep temperature low & controlled

$$j_{gen} \propto T^{3/2} \exp\left(\frac{1}{2kT}\right)$$

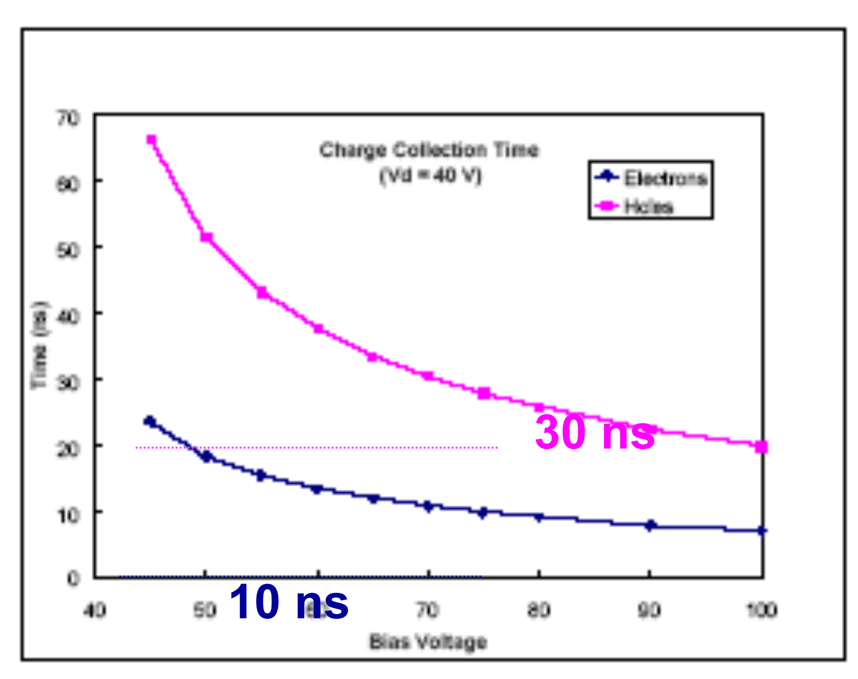
Charge collection

- Electron and hole pairs created in the depletion region move under the E field

$$v_{e,h}(x) = \mu_{e,h} E(x)$$

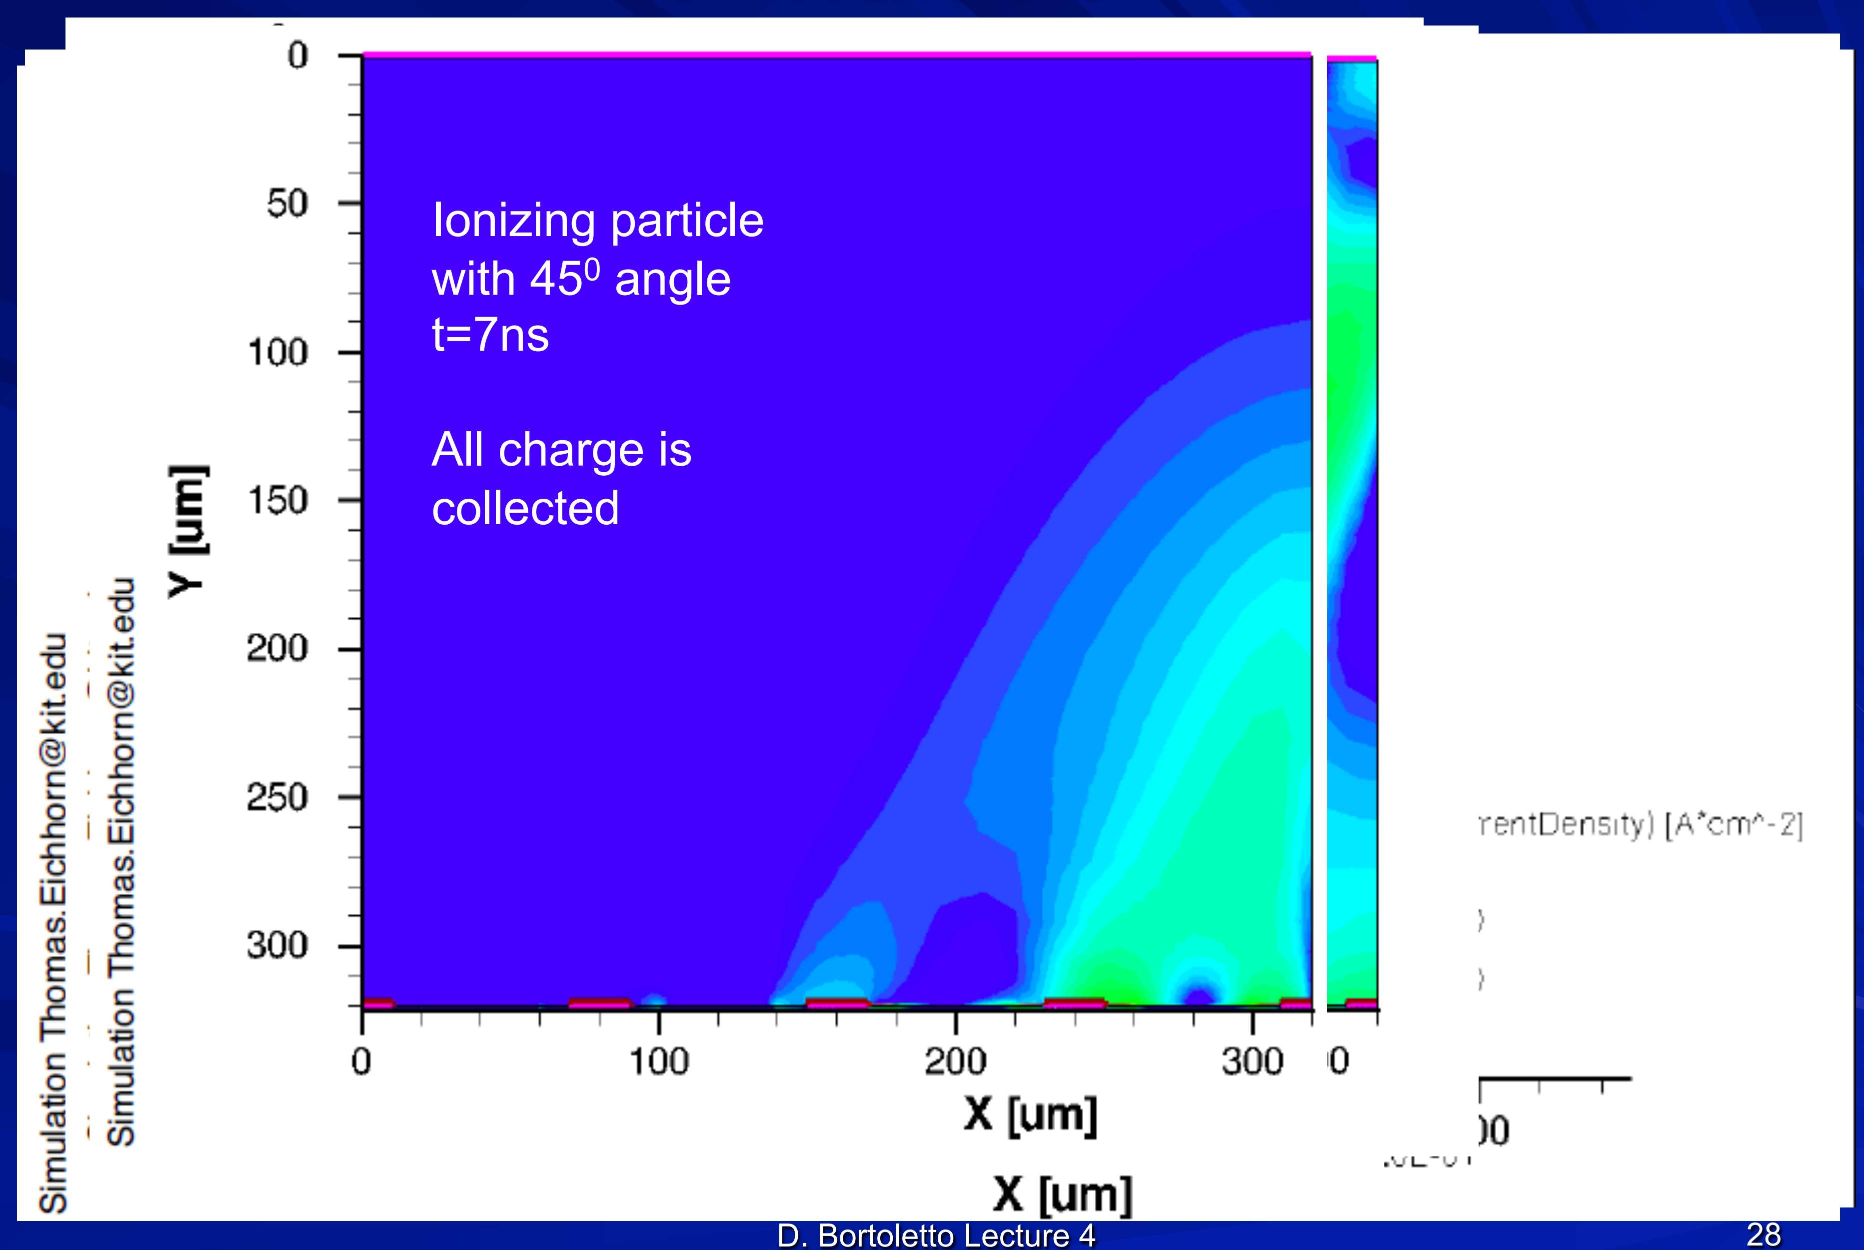
$$\mu_e = 1500 cm^2/Vs, \mu_h = 450 cm^2/Vs$$

- The time required for a carrier to traverse the sensitive volume is the collection time.
- The collection time can be reduced by over-biasing the sensor



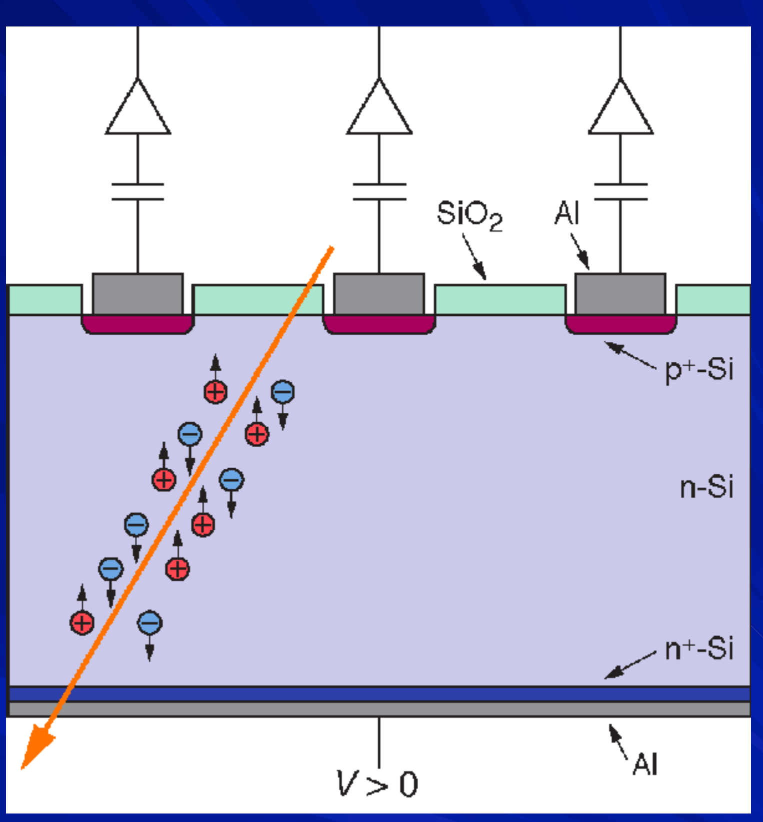
$$t(x) = \frac{D^2}{2\mu_p V_d} \ln\left(\frac{V_{bias} - V_{fd}}{V_{bias} - V_{fd} + 2V_{fd}\left(1 - \frac{x}{D}\right)} \right)$$

Simulation



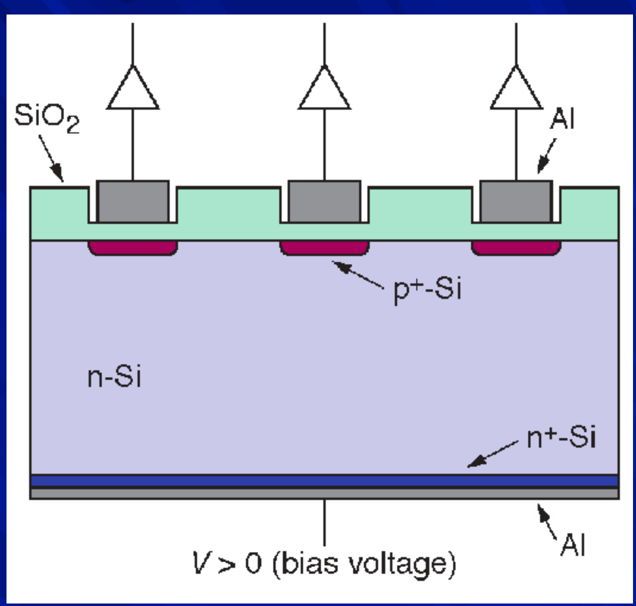
Position Resolution – Strip Detector (DC coupled)

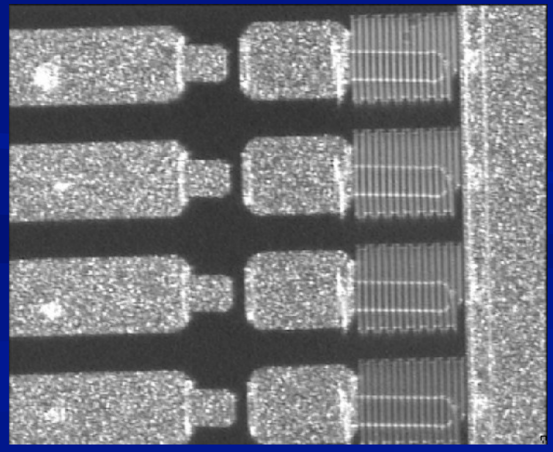
- By segmenting the implant we can reconstruct the position of the traversing particle in one dimension
- DC-coupled strip detector – simplest position sensitive Silicon detector
- Standard configuations
  - Strips p implants
  - Substrate n doped (~2-10 kΩcm) and ~300μm thick
  - $V_{dep} < 200$ V
  - Backside Phosphorous implant to establish ohmic contact and to prevent early breakdown
- Highest field close to the collecting electrodes where most of the signal is induced

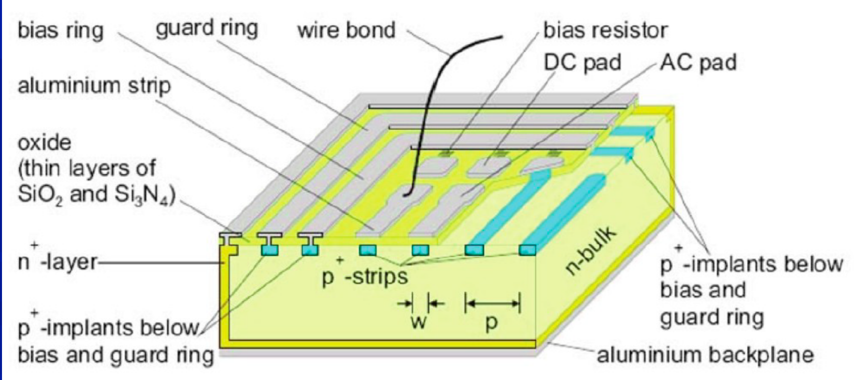


Position Resolution – Strip Detector (AC coupled)

- AC coupling blocks DC leakage current
- Integration of coupling capacitances in standard planar process.
  - Deposition of SiO_2 with a thickness of 100–200 nm between p+ and aluminum strip
  - Increase quality of dielectric by a second layer of Si3N4.
- Long poly silicon resistor with R>1MΩ to connect the bias voltage to the strips:







A typical strip module (CMS)

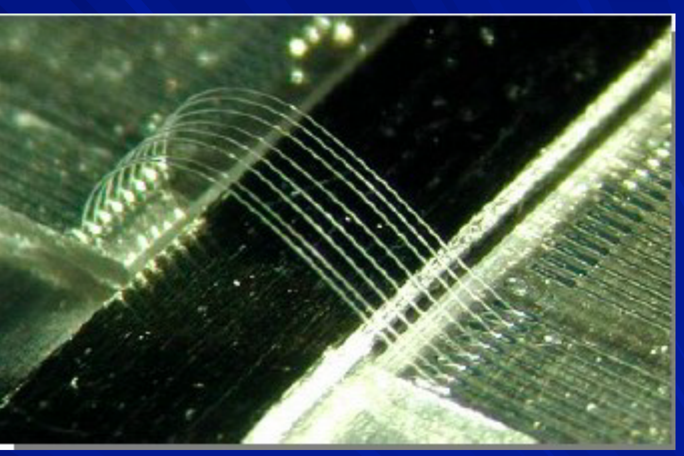
silicon sensors
~20 cm strip length

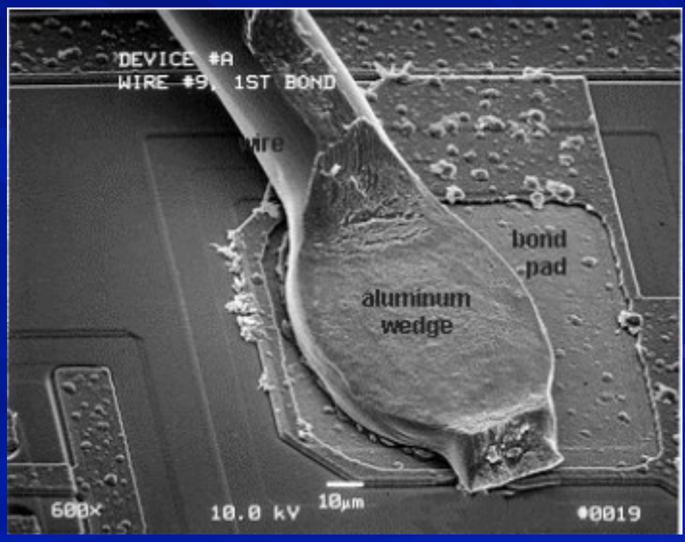
carbon fibre
support

pitch adapter

hybrid
front-end electronics
with read-out chips

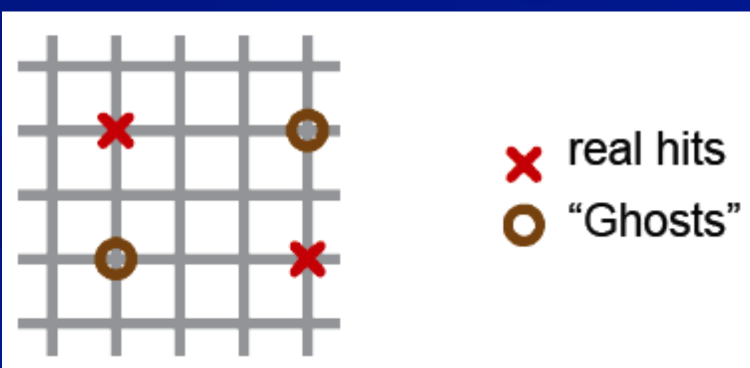
kapton flat cables
for power and data

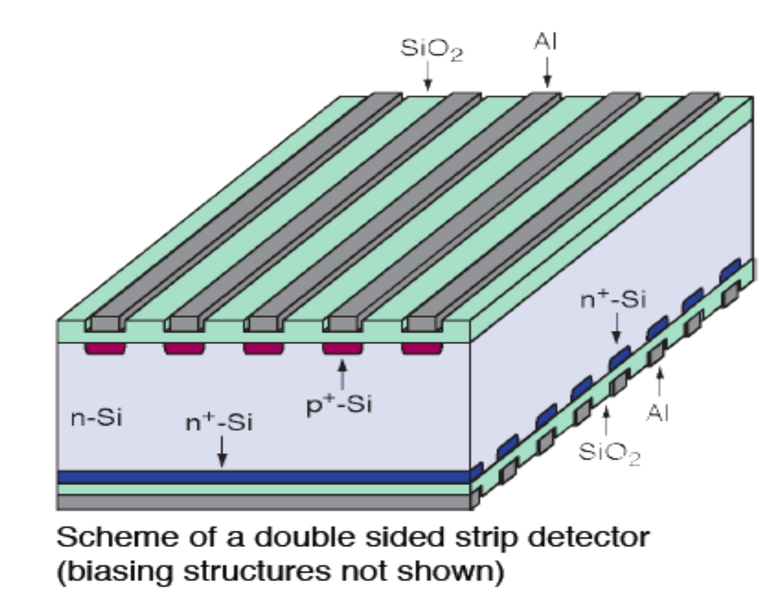




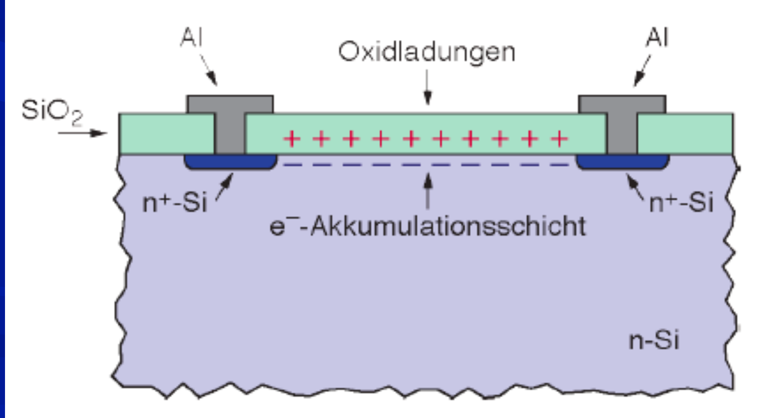
Double Sided Silicon Detectors

- **Advantages:**
  - More elegant way for measuring 2 coordinates than using stereo modules
  - Saves material
- **Disadvantages:**
  - Needs special strip insulation of n-side (p-stop, p-spray techniques)
  - Very complicated manufacturing and handling procedures
- Expensive
- Ghost hits possible





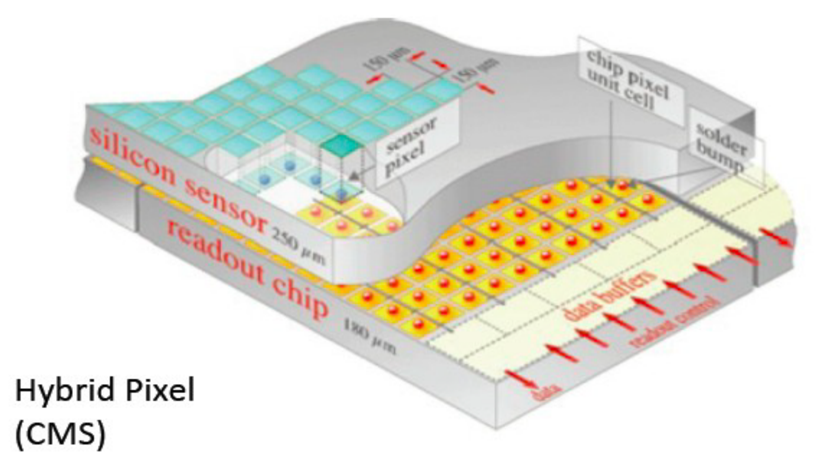
Scheme of a double sided strip detector (biasing structures not shown)

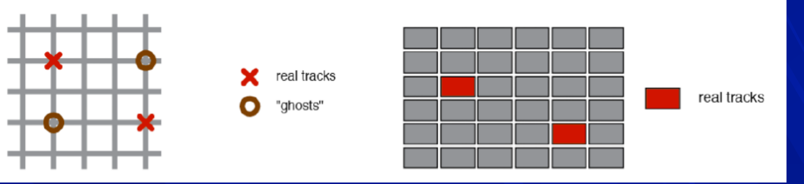


Positive oxide charges cause electron accumulation layer.

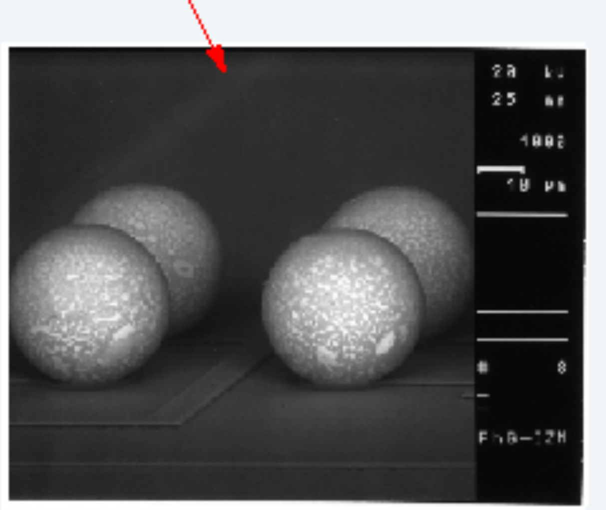
Pixel detector

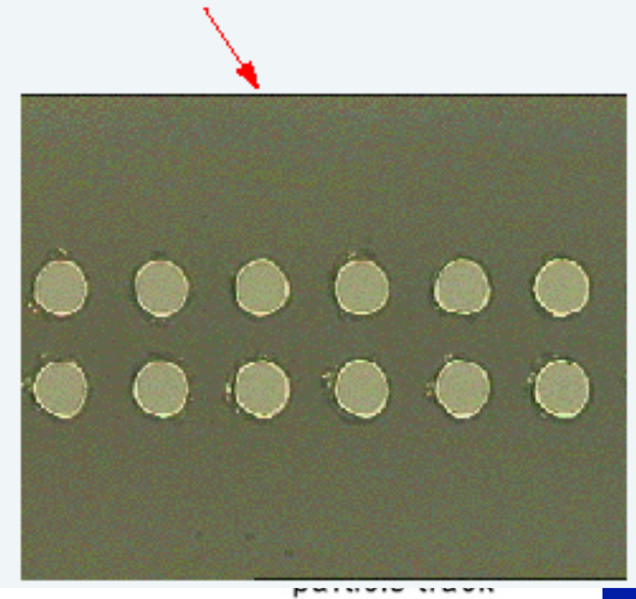
- Advantages
  - Pixel detectors provides space-point information
- Small pixel area
  - low detector capacitance (≈1 fF/ Pixel)
  - large signal-to-noise ratio (e.g. 150:1).
- Small pixel volume
  - low leakage curre
- **Disadvantages:**
  - Large number of
  - Large number of connections
  - Large bandwidth
  - Large power cons





fine pitch (50 µm) bump placements
solder
indium





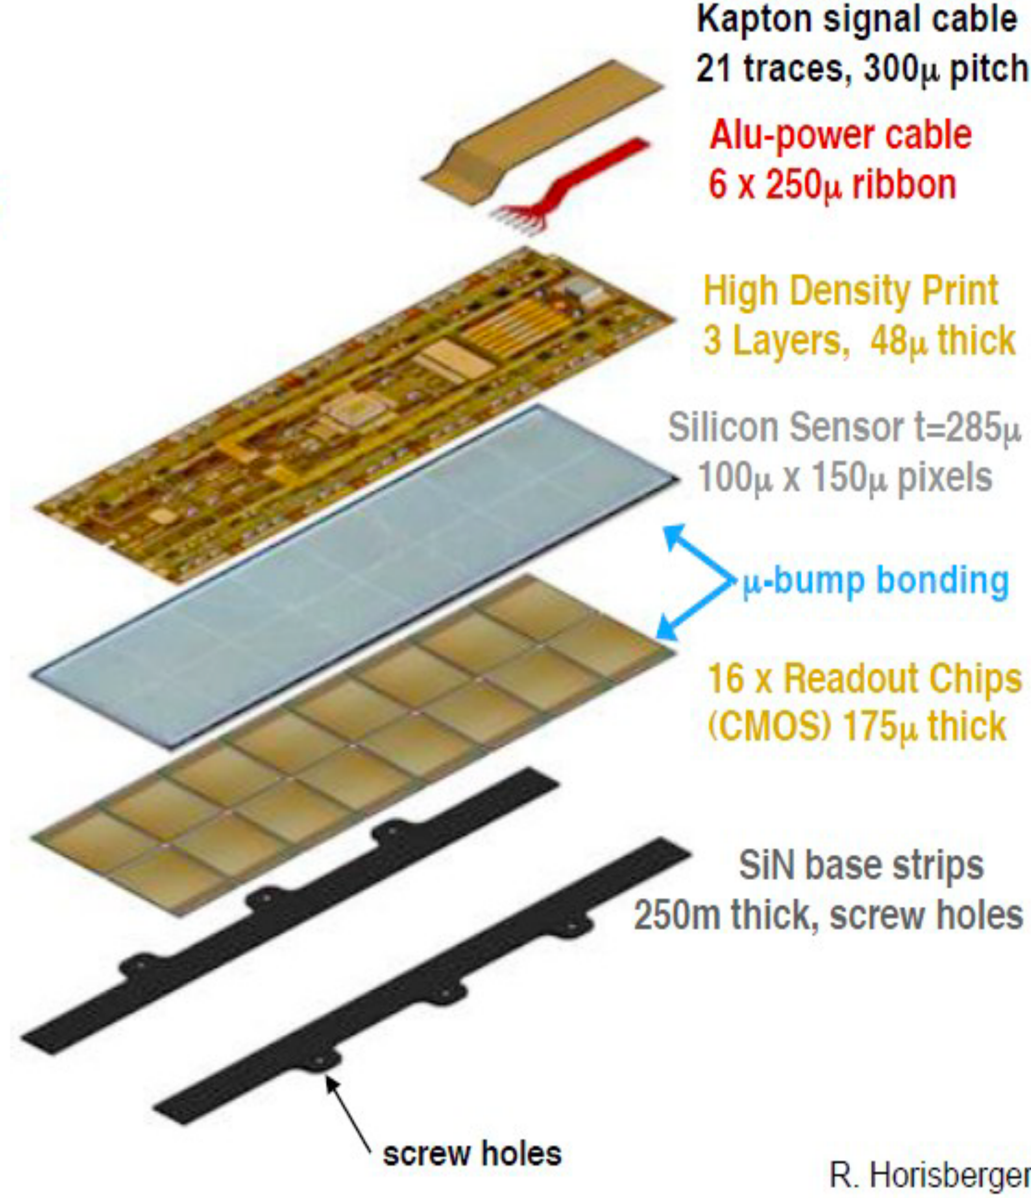
Hybrid Pixel Module for CMS

Sensor:

- Pixel Size: 150mm x 100mm
  - Resolution $\sigma_{r\text{-}\varphi}$ ~ 15μm
  - Resolution σ_z ~ 20μm
- n+-pixel on n-silicon design
  - Moderated p-spray → HV robustness

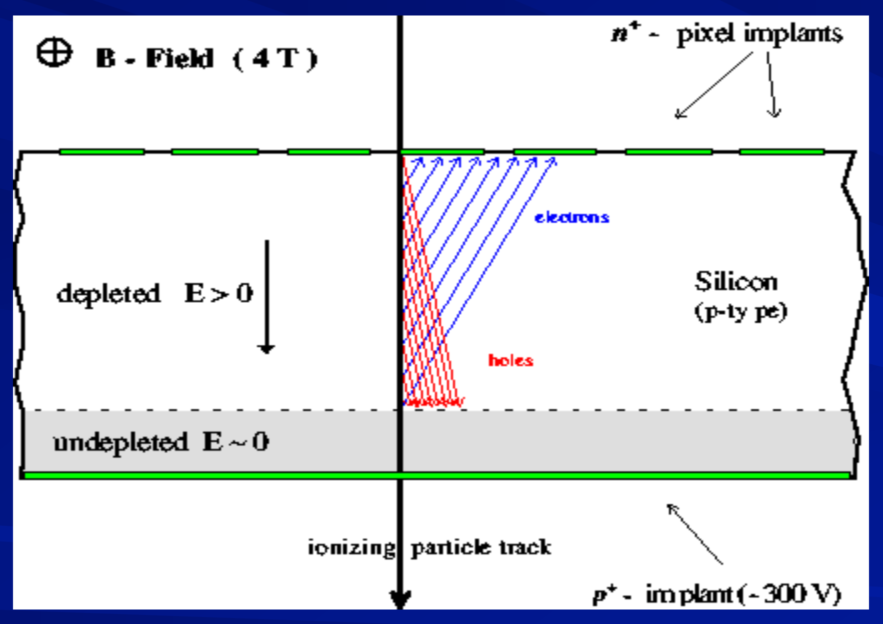
Readout Chip:

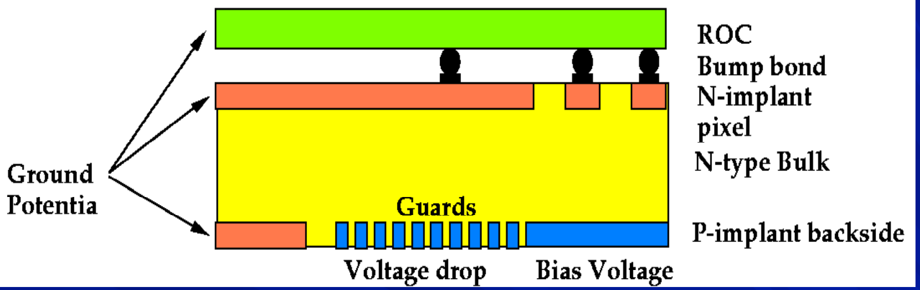
- Thinned to 175μm
- 250nm CMOS IBM Process
- 8" Wafer

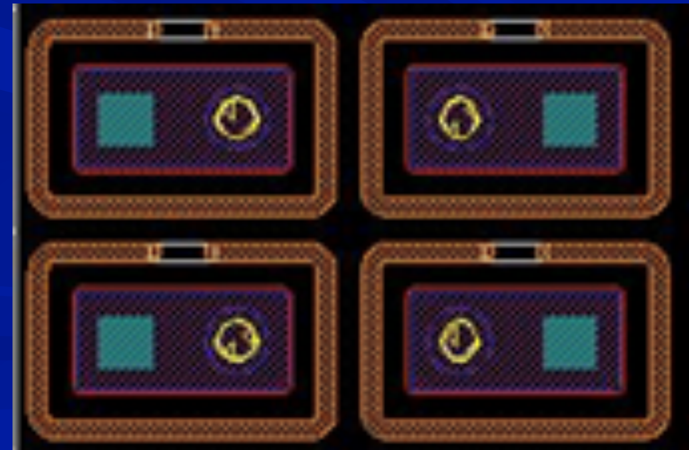


CMS Pixel Sensors

- Baseline CMS design: n^+-n pixels for partial depletion operation and increased Lorentz angle in high B field.
  - 78 μm n^+-implants.
  - P-spay or open p-stops rings provide isolation

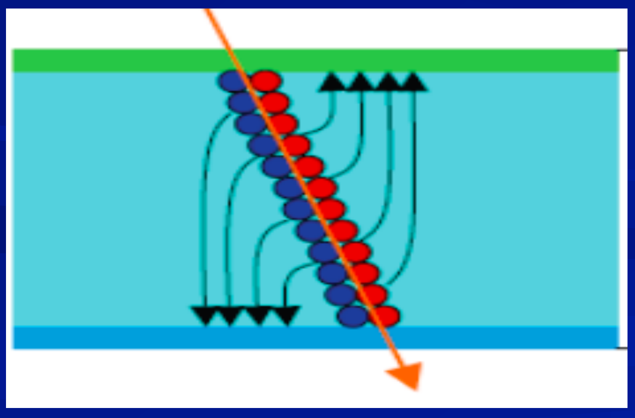






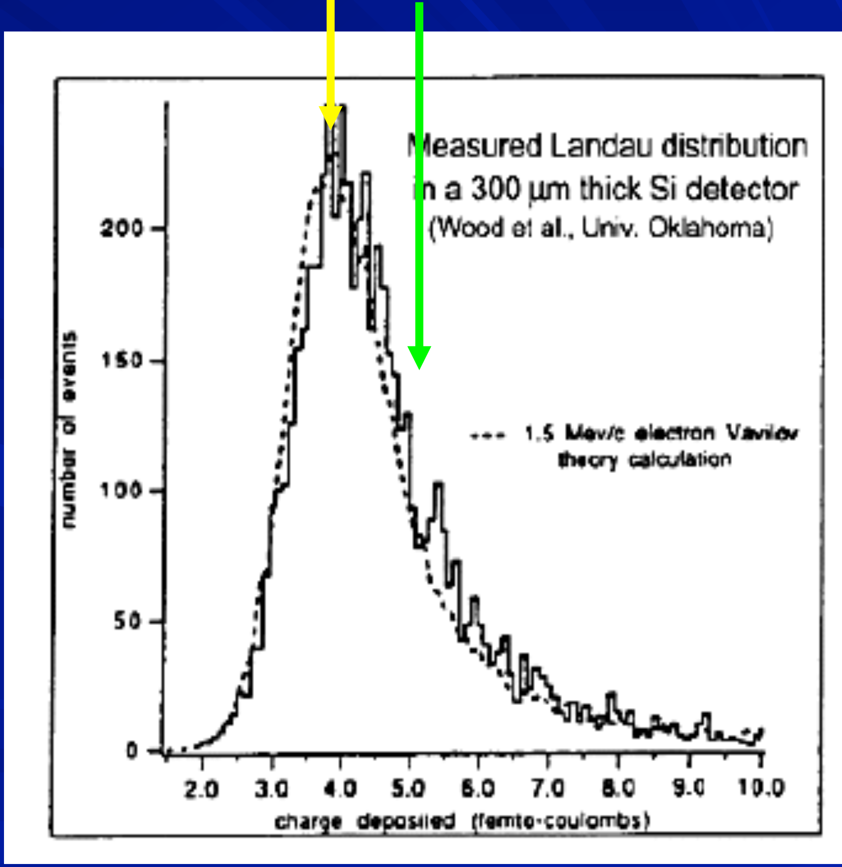
Signal

- **The signal** generated in a silicon detector depends essentially only on the thickness of the depletion zone and on the dE/dx of the particle.
  - The distribution is given by the Landau distribution
  - Since the mean energy loss per cm is 3.87 MeV/cm
  - For 300 μm silicon the most probable charge is ≈ 23400 e-/h pairs



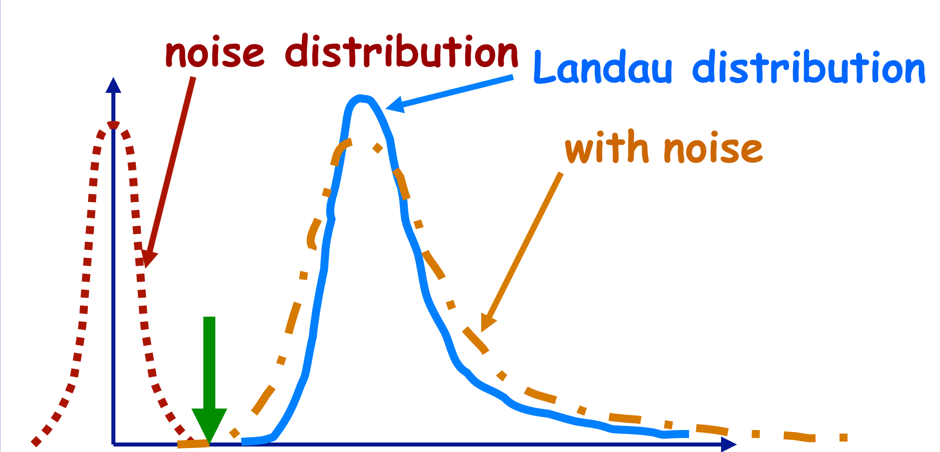
Most probable charge ≈ 0.7× mean

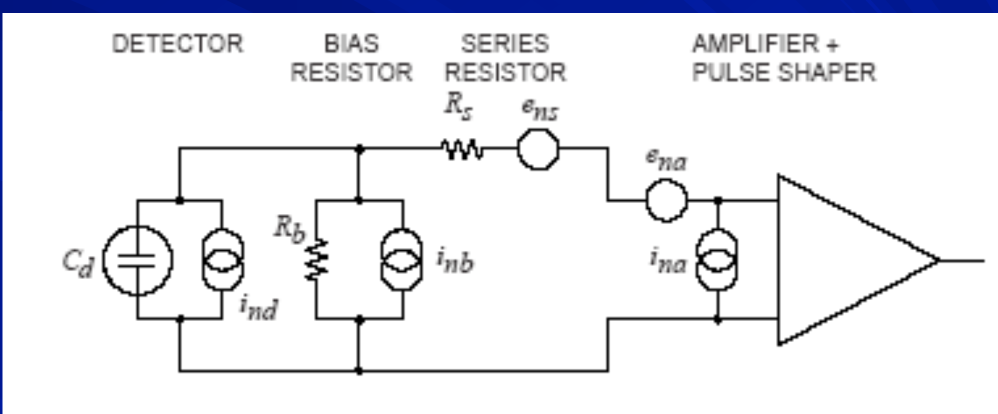
Mean charge



Noise

- **The noise depends on**: geometry of the detector, the biasing scheme, the readout electronics..
- Noise is typically given as "equivalent noise charge" ENC. This is the noise at the input of the amplifier in elementary charges.
- The most important noise contributions are:
  - Leakage current
  - Detector capacitance
  - Detector parallel resistor
  - Detector series resistor
- The overall noise is the quadratic sum of all contributions:





$$ENC = \sqrt{ENC_C^2 + ENC_I^2 + ENC_{Rp}^2 + ENC_{Rs}^2}$$

S/N optimization

- Silicon sensors have low occupancy $\Rightarrow$ most channels have no signal. Good hits are select by requiring N_{ADC}> noise tail. If cut is too high $\Rightarrow$ efficiency loss
- Typical Values for strip detectors is N/S> 10-15. Radiation damage severely degrades the S/N. Thus S/N determines lifetime of the detector in a harsh radiation environment
- To achieve a high signal to noise ratio:
  - Low detector capacitance (i.e. small pixel size or short strips)
  - Low leakage current
  - Large bias resistor
  - Short and low resistance connection to the amplifier
  - Long integration time
- The optimal design depends on the application
- **For pixel detectors the important parameter is the S/Threshold. The threshold in current detectors is of the order of 2500 e^-.**

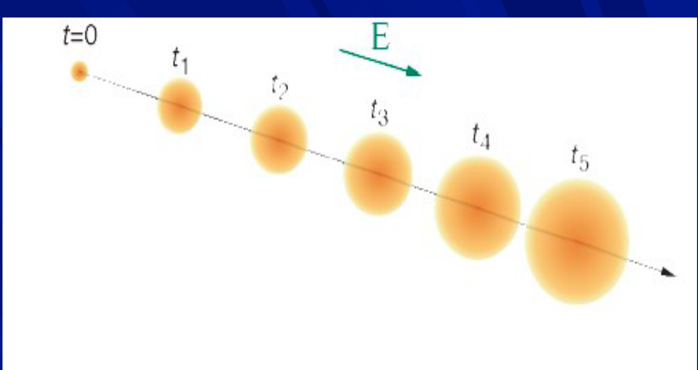
Diffusion

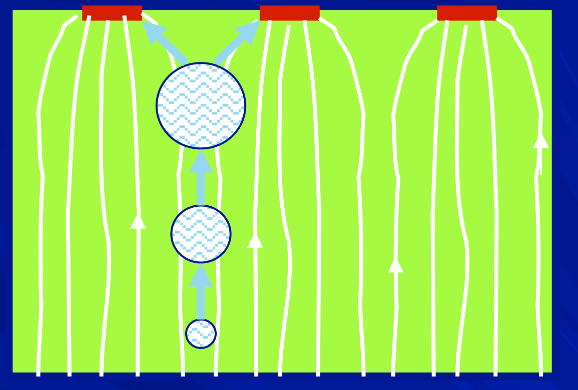
- Diffusion is caused by random thermal motion
- Width of charge cloud after a time t given by

$$\sigma_D = \sqrt{2Dt} \qquad \text{with} \quad D = \frac{kT}{e}\mu$$

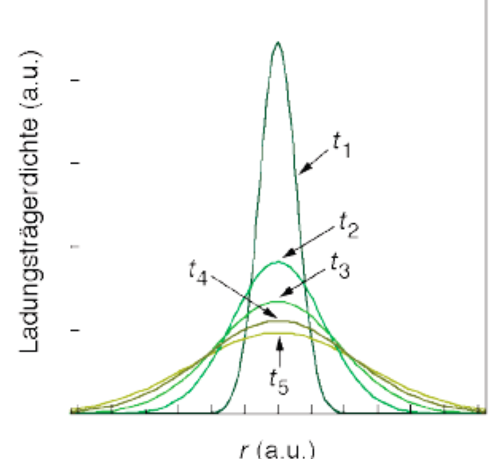
- Drift time for: d=300 μm, E=2.5KV/cm:

  $t_d(e)$ = 9 ns, $t_d(h)$=27 ns
- Diffusion: Typical value: 8 μm for 300 μm drift.
- Can be exploited to improve position resolution





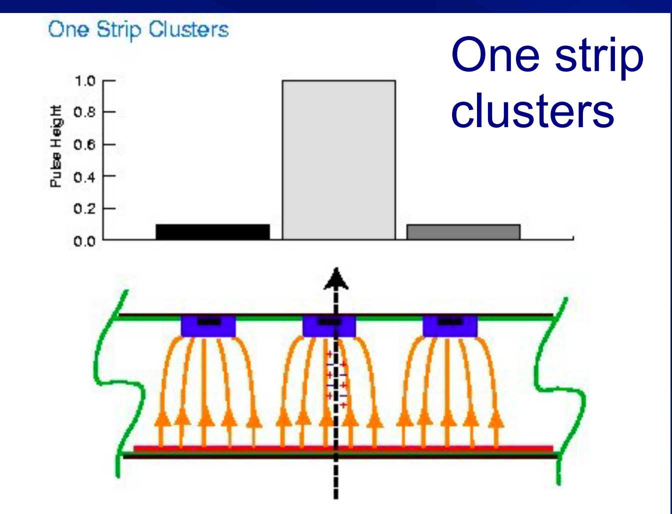
Charge density distribution for 5 equidistant time intervalls:



σ_D=width "root-mean-square" of the charge carrier distribution
t=drift time
K=Boltzman constant
e=electroncharge
D=diffusion coefficient
T=temperature
μ=mobility **μ_e= 1350 cm^2 / V·s, μ_h= 450 cm^2 / V·s**

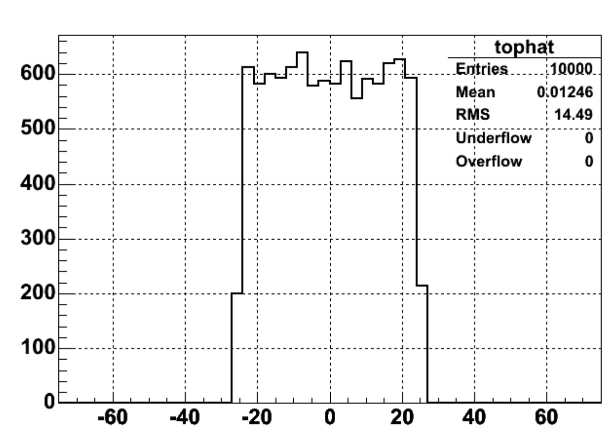
Position resolution

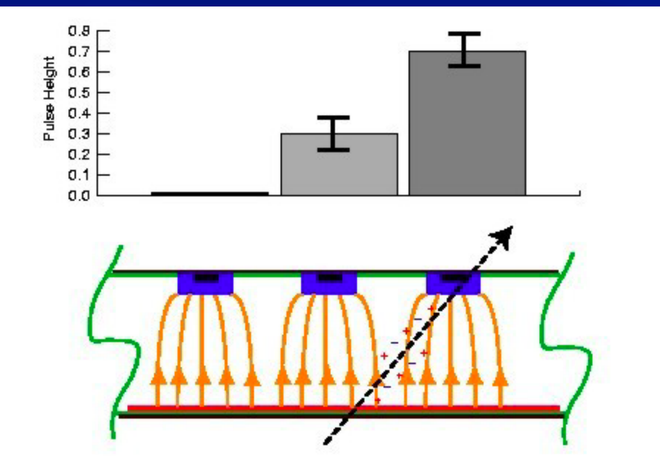
- Resolution is the spread of the reconstructed position minus the true position



One strip clusters

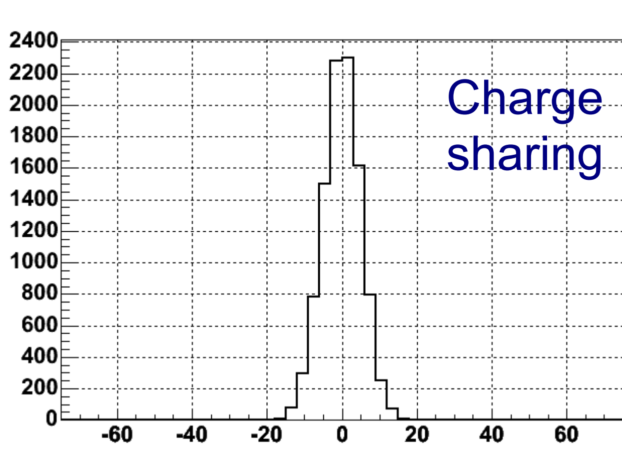
$$\sigma = \frac{pitch}{\sqrt{12}}$$





$$\sigma \approx \frac{pitch}{1.5 \cdot \sqrt{12}}$$

$$\eta = \frac{PH_R}{PH_L + PH_R}$$

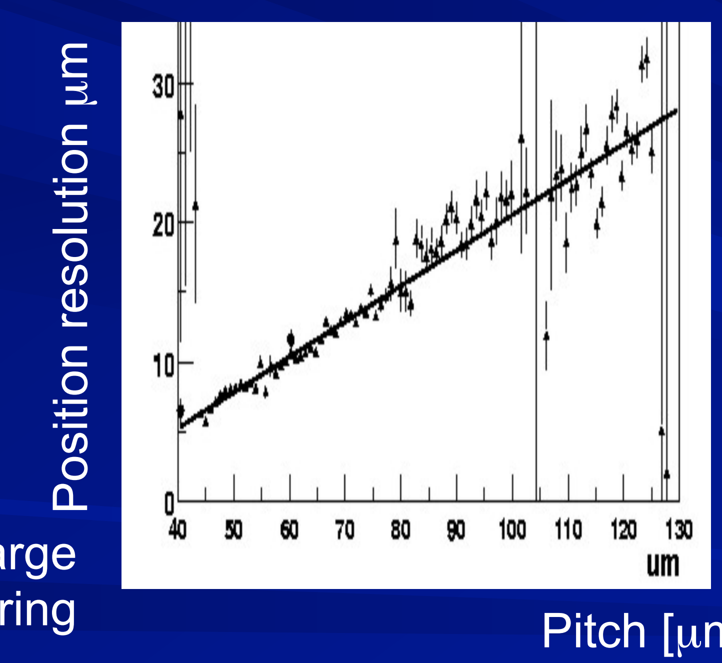


Charge sharing

Position resolution

- Position resolution is degraded by many factors
- Relationship of strip pitch and diffusion width (typically 25-150 μm and 5-10 μm)
- Statistical fluctuations on the energy deposition
- Typical position resolution s for a 300μm thick sensor with S/N=20

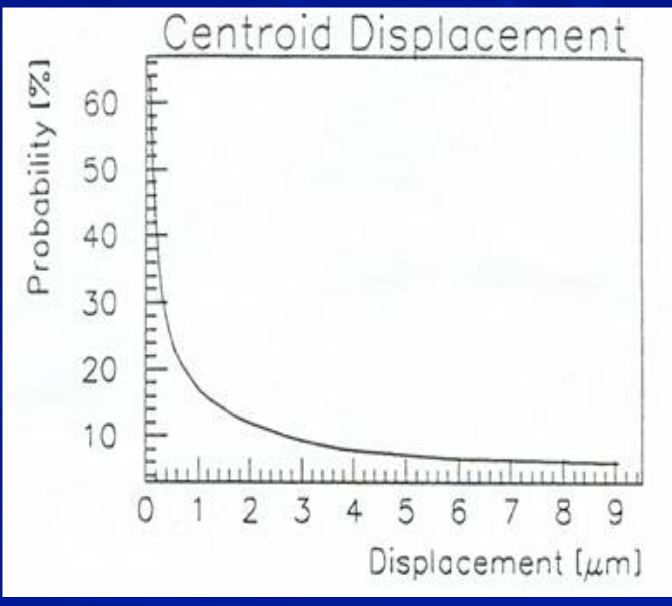
Position resolution μm



Charge sharing

Pitch [μm]

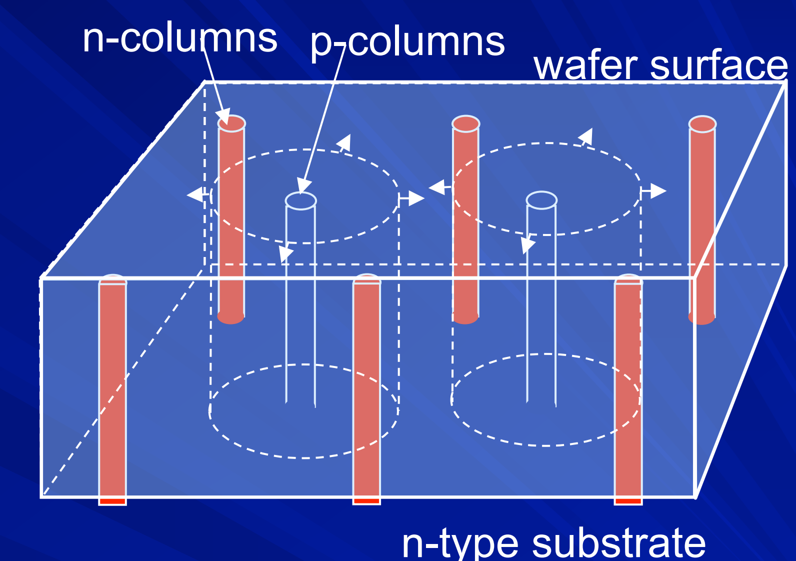
Single strip resolution dominates

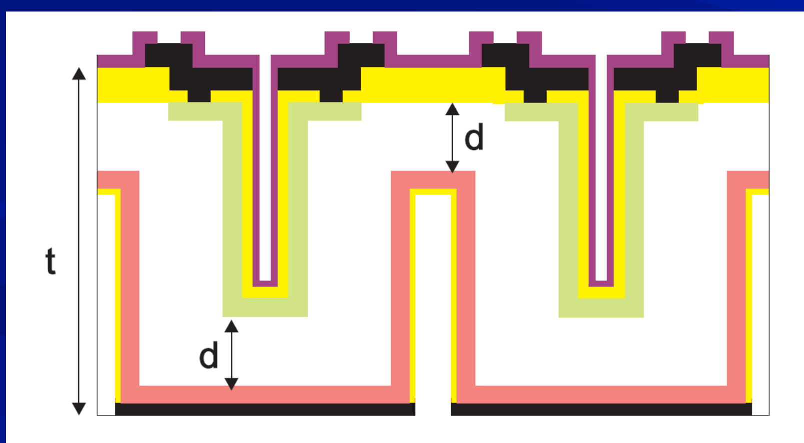


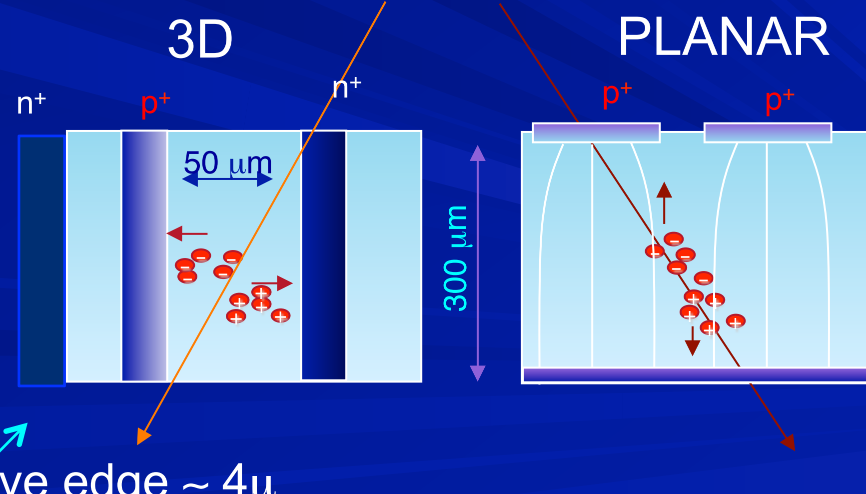
Low probability δ(E) release additional electrons drifting perpendicularly to the track and spoiling position resolution

Ultra radiation hard detectors: 3D

- Shorter drift distance and fast collection
- Lower depletion voltages
- Better radiation tolerance
- Sensor edge can be an electrode (Interesting for forward physics experiments)
- Inefficient in electrode area
- Non standard manufacturing
  - Deep Reactive Ion Etching (DRIE)
  - Unknown yield & costs
- On going effort on industrialization

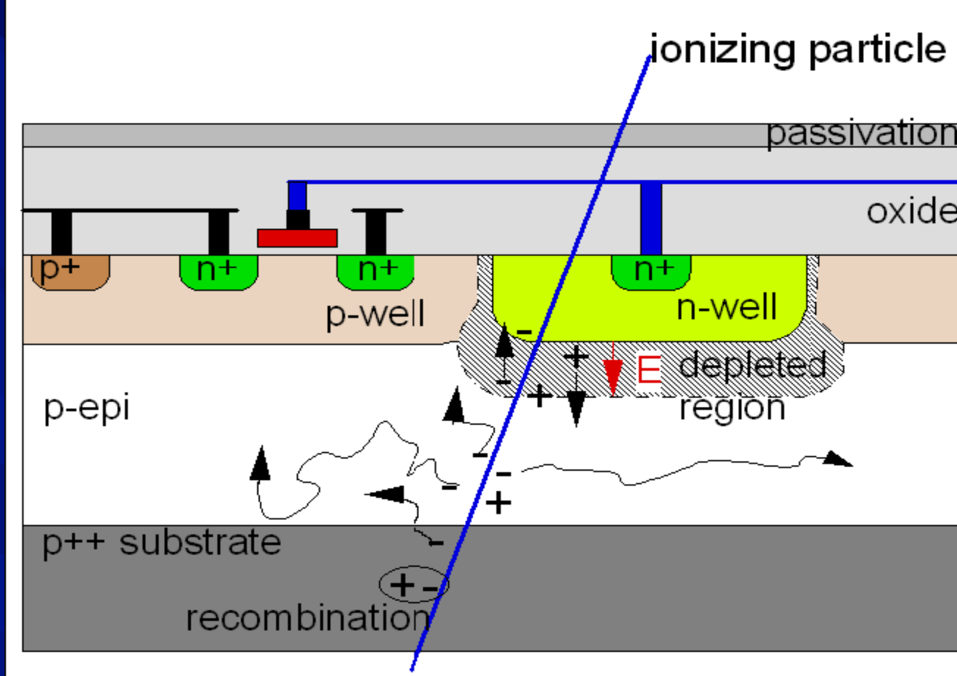






Active edge ~ 4µ

Monolithic Pixels



- Sensors and ROC in the same wafer
- Signal is created in epitaxial layer (10-15 μm e.g. AMS 0.35 μm)
  - Q~ 80 e-h / μm → signal <1000 e−
- Q collection (thermally) to diode with help of reflection on boundaries with p-well and substrate (high doping)
- Advantages of CMOS sensors:
  - Signal processing circuits integrated on sensor substrate (system-on-chip)
  - Sensitive volume (epitaxial layer) is 10–15 μm thick
  - Standard, massive production, fabrication technology → cheap, fast turn-around
  - small pixel sizes(pitch 20 –30 μm)→few μm resolution!
- BUT :
  - Very thin sensitive volume impact on signal magnitude
  - Sensitive volume almost un-depleted impact on radiation tolerance & speed

Different pixel technologies

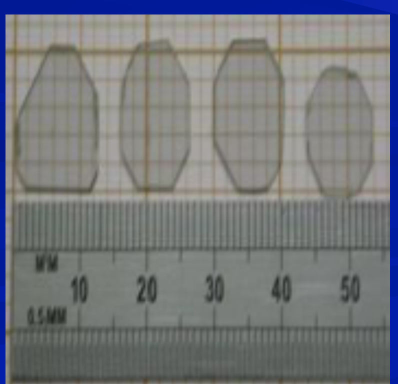
Ultra-radiation hard: Diamond

- Poly crystalline and single crystal
- Competitive (to Si), used in several radiation monitor detectors
- Large band gap (x5 Si)
  - no leakage current
  - no shot noise
- Smaller ε_r (x 0.5 Si)
  - lower input capacitance
  - lower thermal and 1/f noise
- Small Z=6 →large radiation length (x2 in g/cm^2)
- Narrower Landau distribution (by 10%)
- Excellent thermal conductivity (x15)
- Large w_i (x 3.6) →smaller signal charge

- poly-CVD diamond wafers can be grown >12 cm diameter, >2 mm thickness.
- Wafer collection distance now typically 250μm (edge) to 310μm (center).
- 16 chip diamond ATLAS modules

- sc-CVD sensors of few cm^2 size used as pixel detectors
- High quality scCVD diamond can collect full charge for thickness 880μm



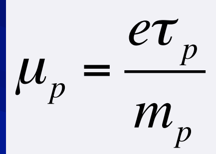
Summary of material properties

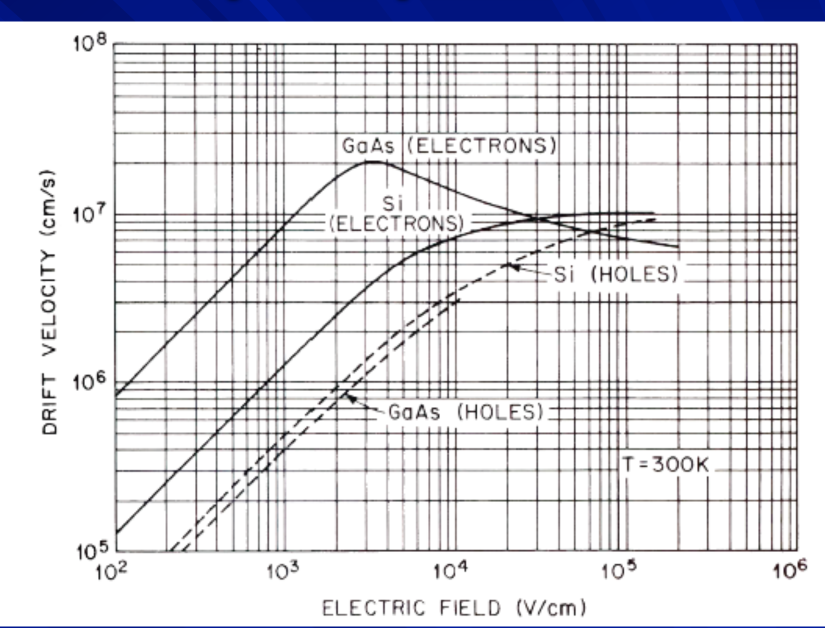
- **Drift velocity** for electrons: $\vec{v}_n = -\mu_n \cdot \vec{E}$

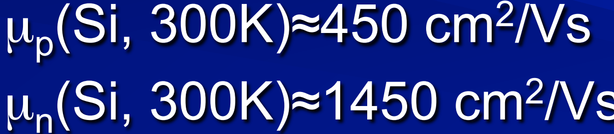
  for holes: $\vec{v}_p = -\mu_p \cdot \vec{E}$

- **Mobility** for electrons: $\mu_n = \frac{e\tau_n}{m_n}$

  for holes: $\mu_p = \frac{e\tau_p}{m_p}$







μ_p(Si, 300K)≈450 cm^2/Vs

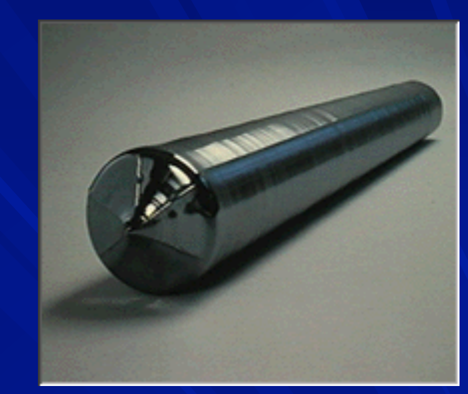
μ_n(Si, 300K)≈1450 cm^2/Vs

- **Resistivity:**

$$\rho = \frac{1}{e\left(\mu_n n_e + \mu_p n_h\right)}$$

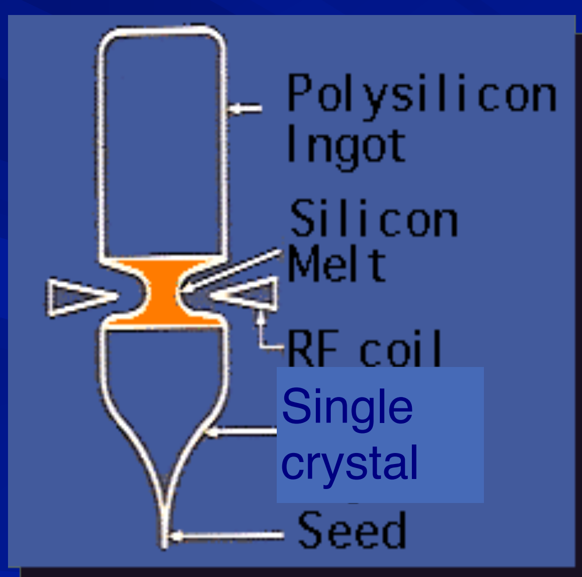
- e= electric charge
- E= external field
- m_n and m_p= effective mass of electrons and holes
- τ_n and τ_p= mean free path of electrons and holes
- n_n and n_p= density of electrons and holes

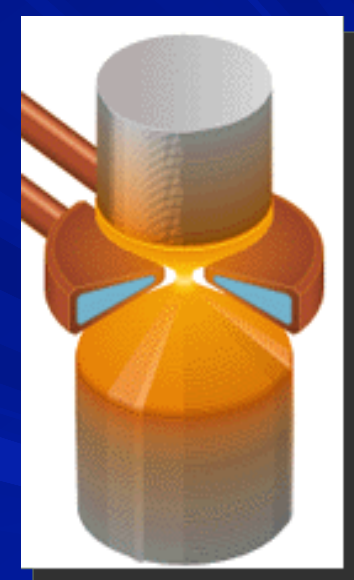
Wafer Fabrication

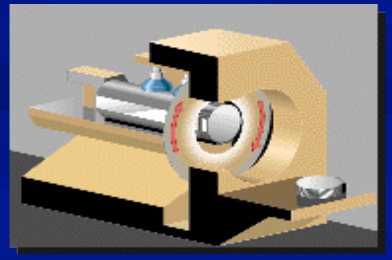


1) Start with very pure quartzite sand. Clean it and further purify by chemical processes. Melt it and add the tiny concentration of phosphorus (boron) dopant to make n(p) type silicon. Pour it in a mold to make a polycrystalline silicon cylinder

2) Using a single silicon crystal seed, melt the vertically oriented polysilicon cylinder onto the seed using RF power to obtain single crystal 'ingot'.







3) Slice ingot into wafers of thickness 300- 500μm with diamond encrusted wire or disc saws.

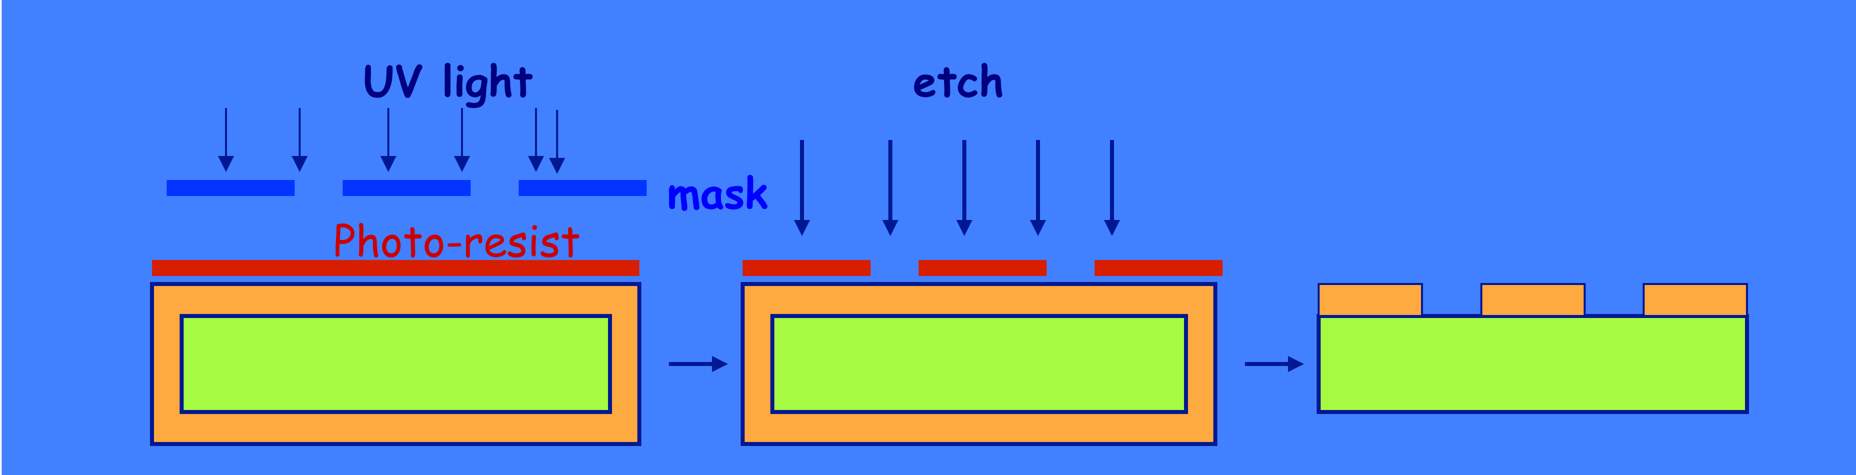
Diode Processing

animation

1) Start with n-doped silicon wafer, $\rho \approx$ 1-10 kΩcm. Silicon can be turned into n-type by neutron doping ($^{30}Si+n \rightarrow {}^{31}Si$, $^{31}Si \rightarrow {}^{31}P+\beta^{-}+\nu$)

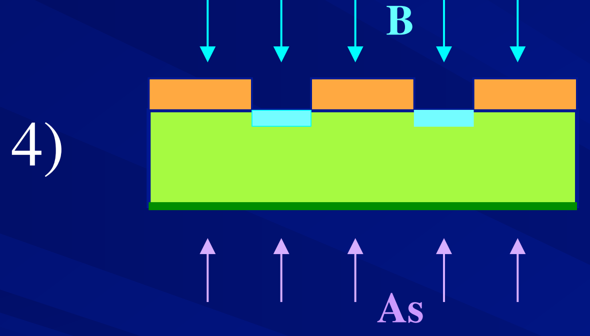
2) Oxidation at 800 - 1200°C

3) Photolithography (= mask align + photo-resist layer + developing) followed by etching to make windows in oxide



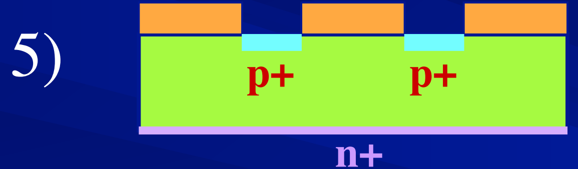
Diode Processing

4)



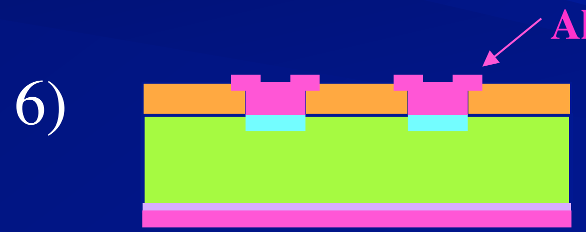
Doping by ion implantation (or by diffusion)

5)



Annealing (healing of crystal lattice) at 600 °C

6)



Photolithography followed by Al metallization over implanted strips and over backplane usually by evaporation.

⇒Simple DC-coupled silicon strip detector

Oxide Charge

- Many defects can appear at the interface between Si and SiO_2.
  - Some of the interface atoms will miss oxygen atoms and create Si-O bonds
  - Impurities (H, OH,N)
- These will create levels that can trap mobile electrons and holes (Interface traps)
- The charge due to the trapped electrons and holes onto the oxide defects is the "oxide charge"
- The oxide charge is usually positive ⇒ electron accumulation layer
- It can affect device characteristics: breakdown voltage, strip isolation, interstrip capacitance

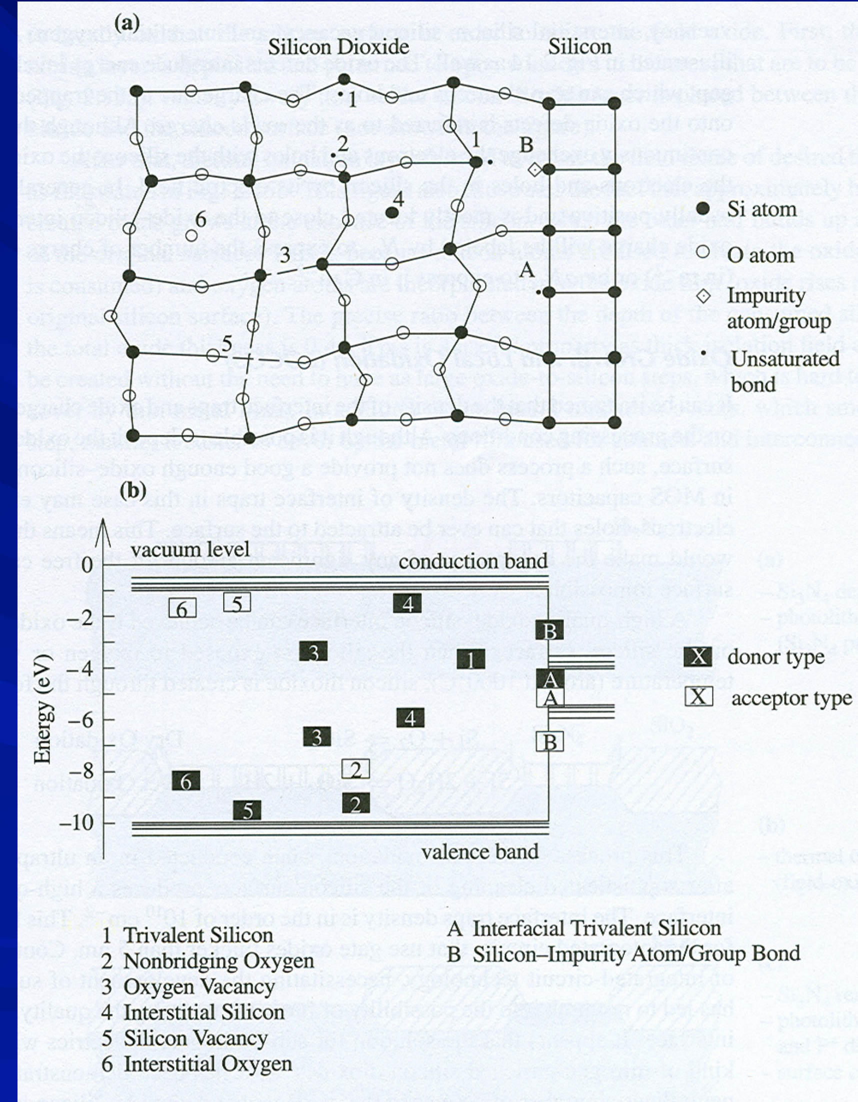


Figure 2.14 Illustration of the oxide–silicon interface and the associated defects: (a) a two-dimensional chemical-bond model and (b) the energy-band model.

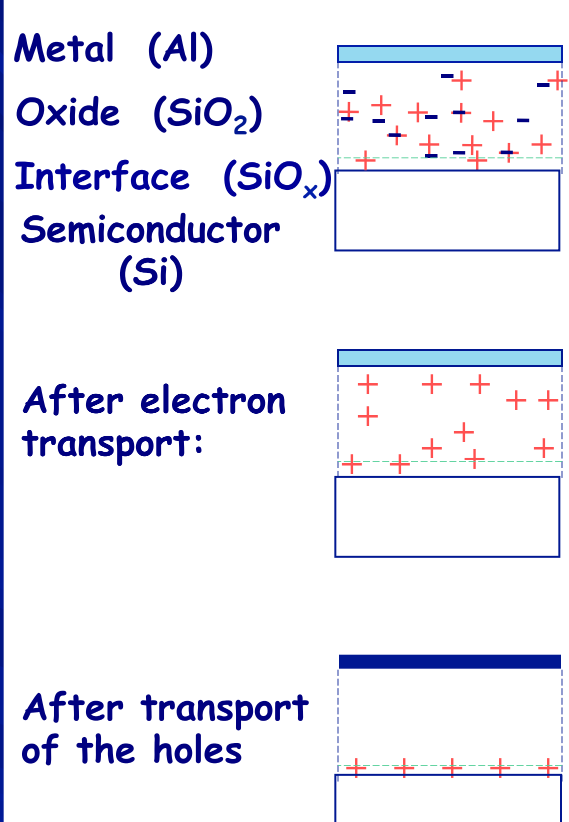
Dimitrijev

Radiation Damage in Silicon

- Two general types of radiation damage
  - "Bulk" damage due to physical impact within the crystal
  - "Surface" damage in the oxide or Si/SiO_2 interface
- Cumulative effects
  - Increased leakage current (increased shot noise)
  - Silicon bulk type inversion (n-type to p-type)
  - Increased depletion voltage
  - Increased capacitance
- Sensors can fail from radiation damage
  - Noise too high to effectively operate
  - Depletion voltage too high to deplete
  - Loss of inter-strip isolation (charge spreading)
- Signal/noise ratio is the quantity to watch

Surface Damage

- **Surface damage generation:**
  - **Ionizing radiation creates electron-hole pairs in the SiO_2**
  - **Many recombine, electrons migrate quickly**
  - **Holes slowly migrate to Si/SiO_2 interface since hole mobility is much lower than for electrons ($20\ cm^2/Vs$ vs. $2x10^5\ cm^2/Vs$)**
  - **Some holes 'stick' in the boundary layer**
- **Surface damage results in**
  - **Increased interface trapped charge**
  - **Increased fixed oxide charges**
  - **Surface generation centers**



- MOS devices are sensitive to surface damage
  - Electron accumulation under the oxide interface can alter the depletion voltage (depends on oxide quality and sensor geometry)
  - In silicon strip sensors, surface damage effects (oxide charge) saturate at a few hundred kRad

Surface Damage Effects

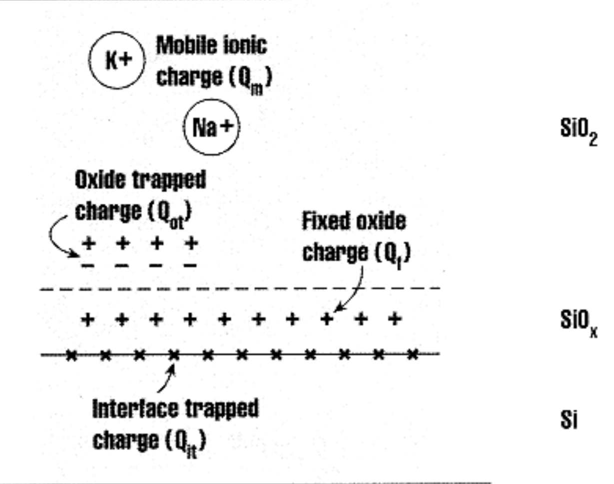


Figure 4-14 Silicon/silicon dioxide structure with mobile, fixed charge, and interface states (©1980.

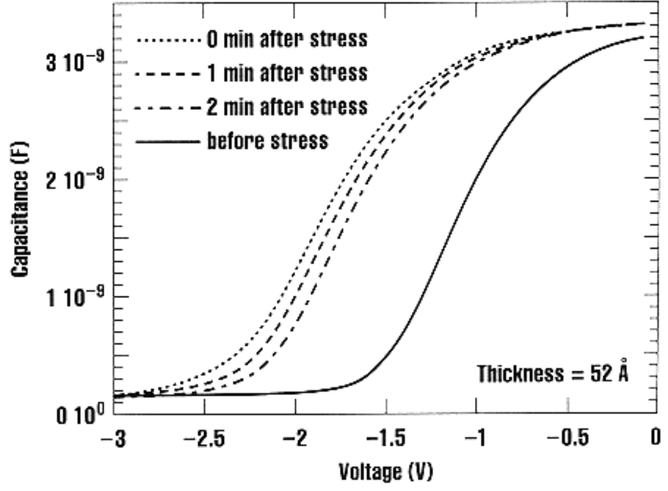

Figure 4-15 High frequency C-V traces showing the effects of interface states and fixed charge.

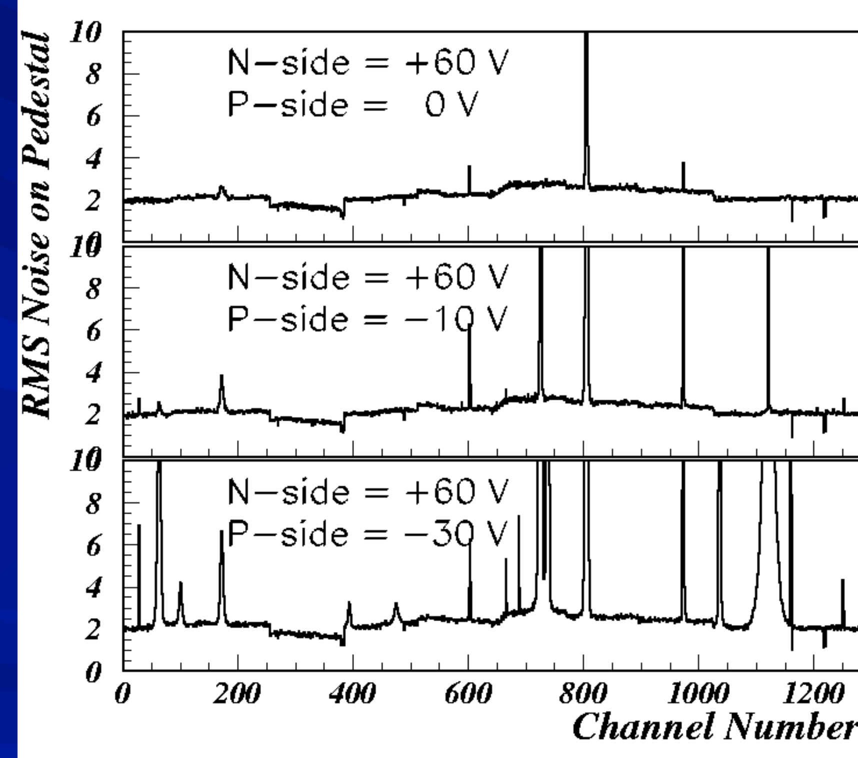
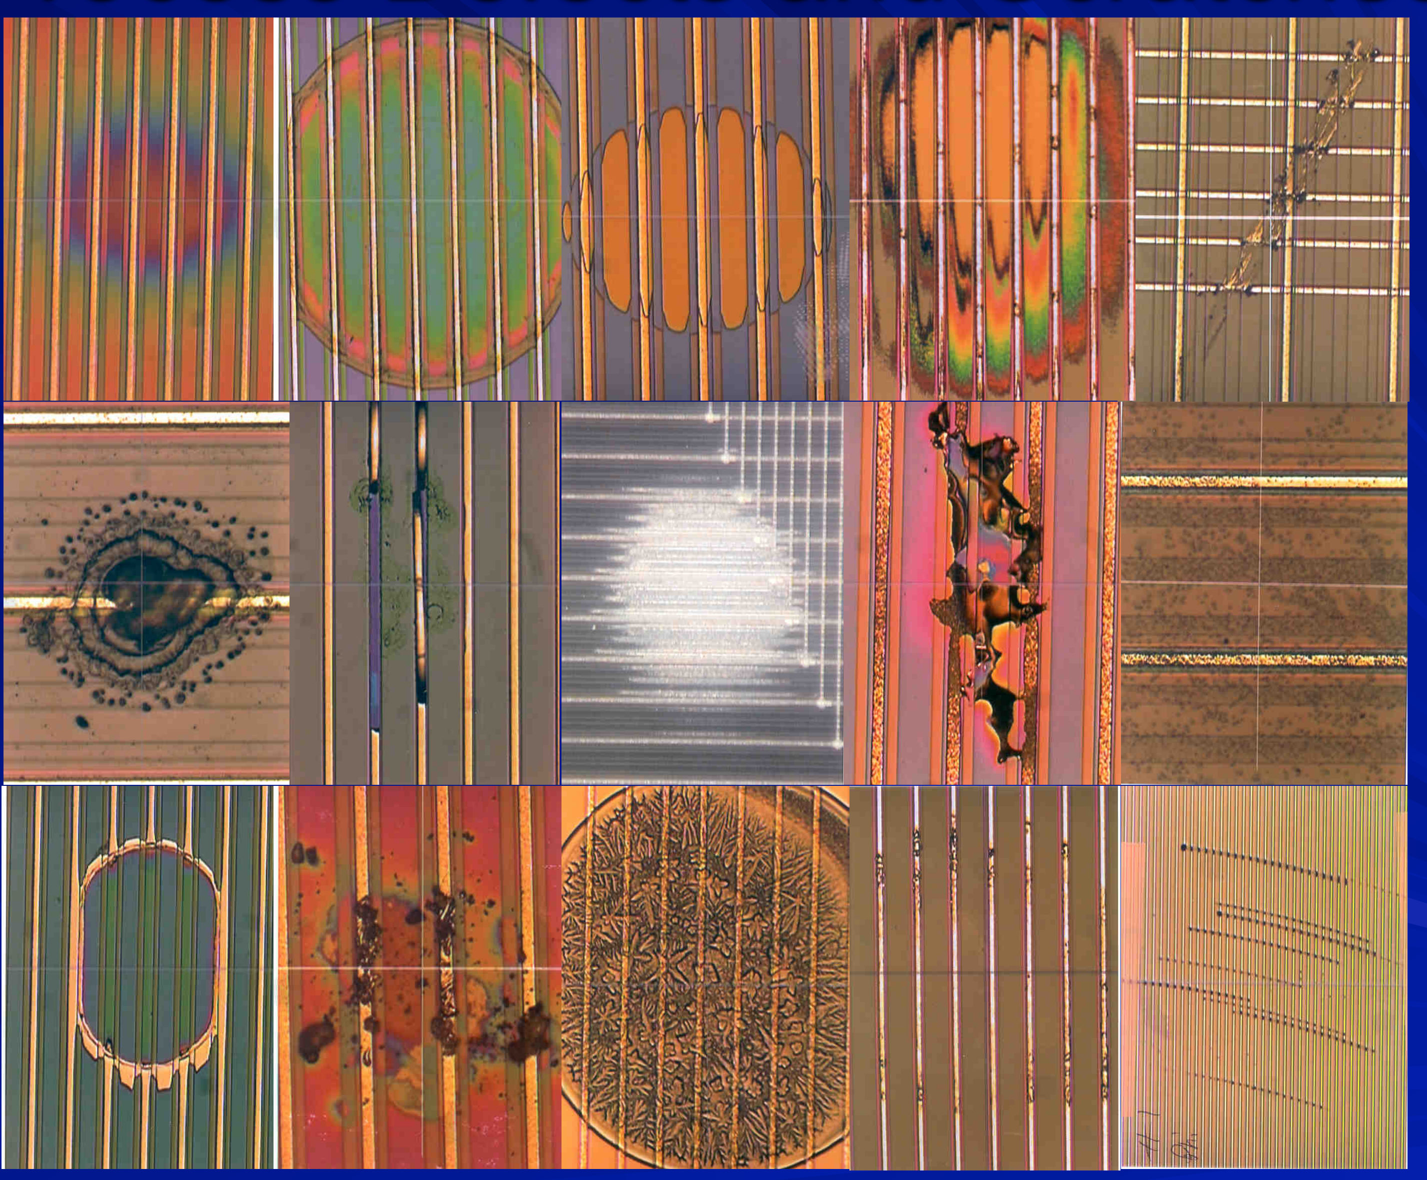
- Charges in the oxide layer can cause:
  - Risk to readout electronics
    - threshold shifts
    - noise and gain deterioration
  - Increase in the sensors capacitances
  - Single event upset in small feature size devices
- Problems can be minimized by:
  - Silicon crystal orientation (<100> rather than <111>) can minimize interface traps at boundary
  - Reducing oxide thickness
    - Voltage shifts are proportional to the square of the thickness (0.25 μm CMOS more rad hard)
  - Processing

Surface Damage

- Oxide charges in the silicon strip sensors depend on vendor
  - Oxide charge starts out high before irradiation
  - Adversely influences operation in certain biasing configurations
  - Could set a limit to max bias voltage

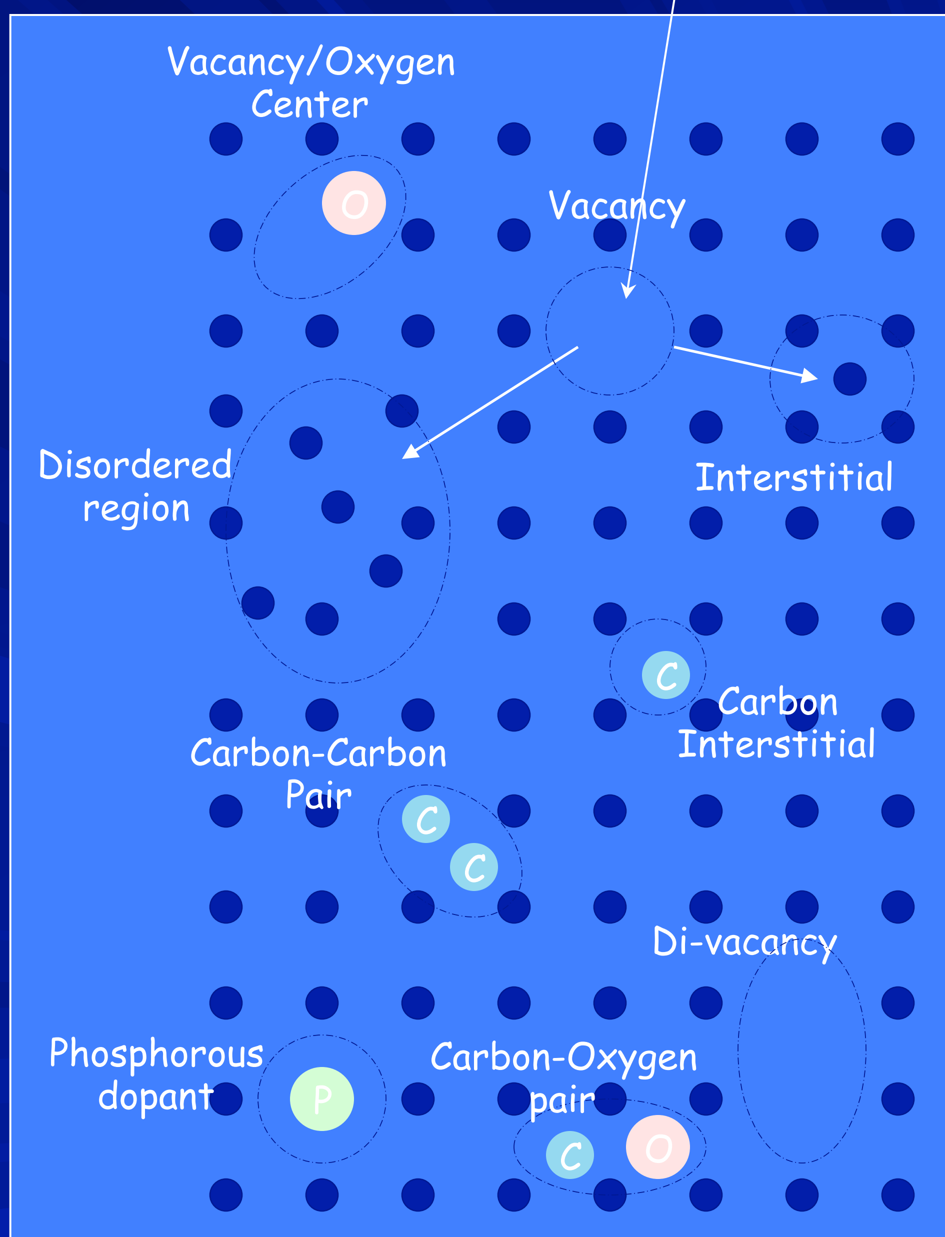


Process Defects and Scratches



Bulk Damage

- Bulk damage is mainly from hadrons displacing primary lattice atoms (for E > 25 eV)
  - Results in silicon interstitial, vacancy, and large disordered region
  - 1 MeV neutron transfers 60-70 keV to recoiling silicon atom, which in turn displaces ~1000 additional atoms
- Defects can recombine or migrate through the lattice to form more complex and stable defects
  - Annealing can be beneficial
  - Defects can be stable or unstable
  - Displacement damage is directly related to the non-ionizing energy loss (NIEL) of the interaction
  - Varies by incident particle type and energy



Bulk Damage

- Displacement damage occurs for all particles
  - Pions and neutrons are typically the most numerous
- Particle flux in a collider environment
  - Experience from CDF Run I suggests $\Phi = \Phi_0/r^{1.7}$
  - Neutron flux falls less rapidly; it eventually becomes significant
- NIEL Radiation damage studies typically normalized to 1 MeV neutron damage equivalent

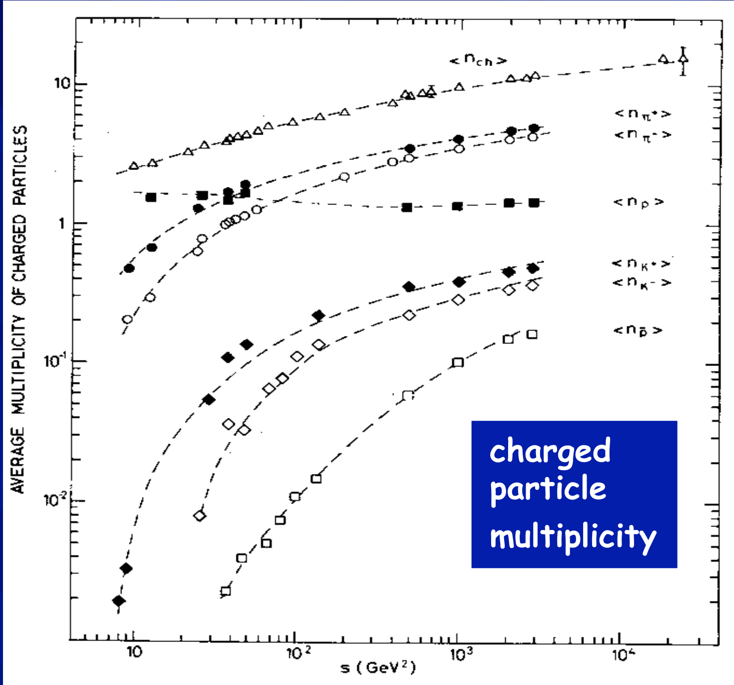


Figure 28 Charged-particle composition in inelastic *pp* collisions as a function of *s*.

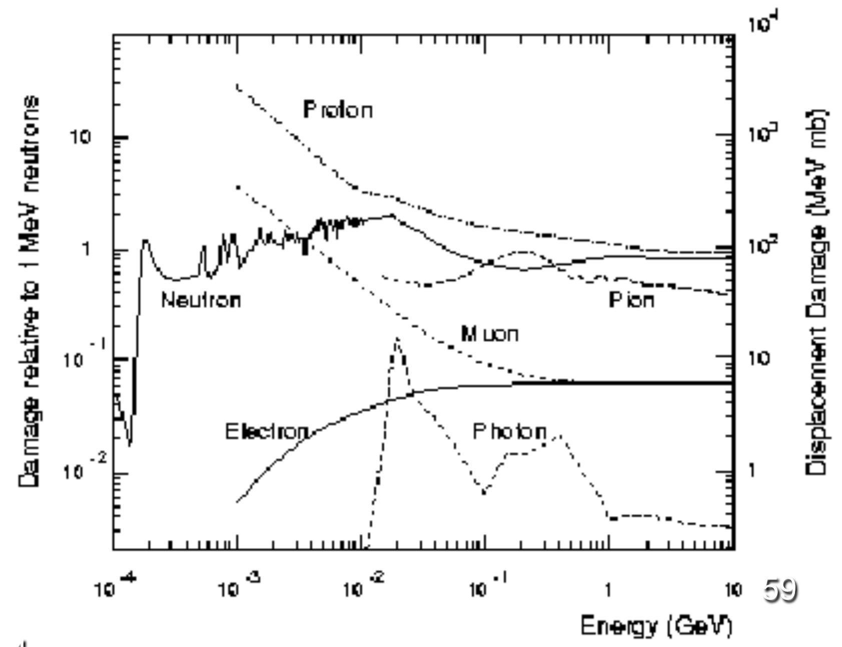


Bulk Damage Effects

- Leakage Current:

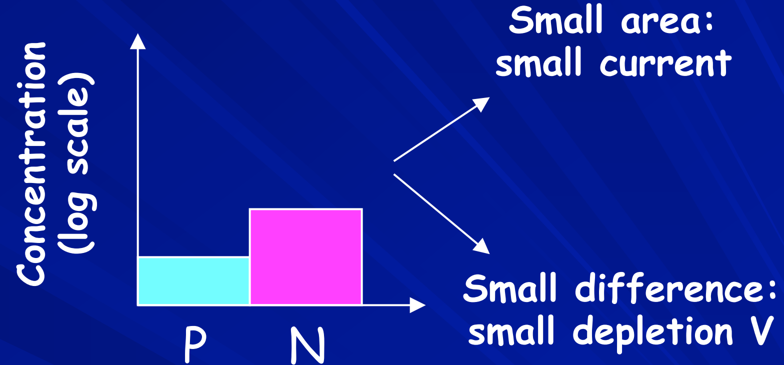
  $\Delta I = \alpha(t)\Phi V$

  - $\alpha(t)$ (damage constant), V (volume), and Φ (fluence).
  - Annealing reduces the current
  - Independent of particle type
- Depletion Voltage:

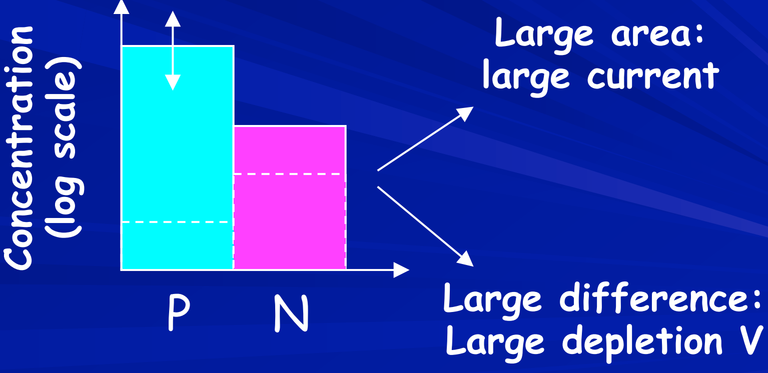
  $V_{dep} = q|N_{eff}|d^2/2\varepsilon\varepsilon_0$

  - Effective dopant concentration ($N_{eff} = N_{donors} - N_{acceptors}$), sensor thickness (d), permitivity ($\varepsilon\varepsilon_0$).
  - Depletion voltage is parameterized in three parts:
    - **Short term annealing (N_a)**
    - **A stable component (N_c)**
    - **Long term reverse annealing (N_y)**

Before Irradiation:



After Irradiation:



Leakage Current

- Defects create intermediate states within the band gap
  - intermediate states act as 'stepping stones' of thermal generation of electron/hole pairs
  - Some of these states anneal away; the bulk current reduces with time (and temperature after irradiation
- Annealing function $\alpha(t)$
  - Parameterized by the sum of several exponentials $\alpha_i \exp(-t/\tau_i)$
  - Full annealing (for the example below) reached after ~1 year at 20ºC
  - At low temperatures, annealing effectively stops
  - Dependant on incident particle type (?)

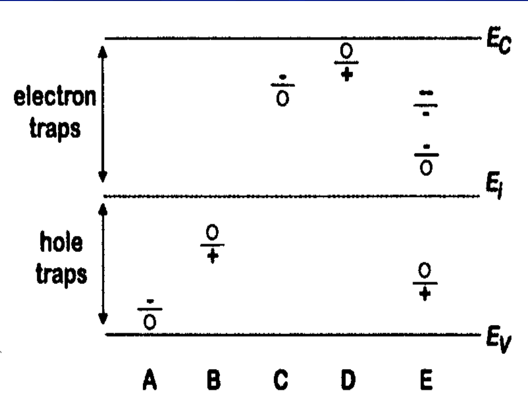


Fig. 3.24 Classification of levels in the forbidden gap.

A: shallow acceptor, e.g. B_s
B: deep donor, e.g. C_iO_i
C: deep acceptor, e.g. VO_i
D: shallow donor, e.g. P_s
E: amphoteric level, e.g. VV

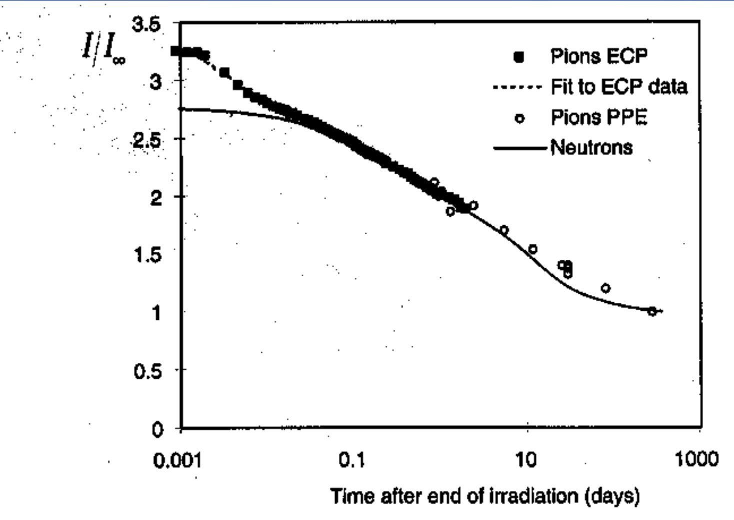

Fig. 2: Short-term current annealing for pions and neutrons following a short (26 min) irradiation. Pion data taken from measurements, neutron curve taken from Ref. [6], (data for detectors before inversion) and recalculated for 26 min irradiation time.

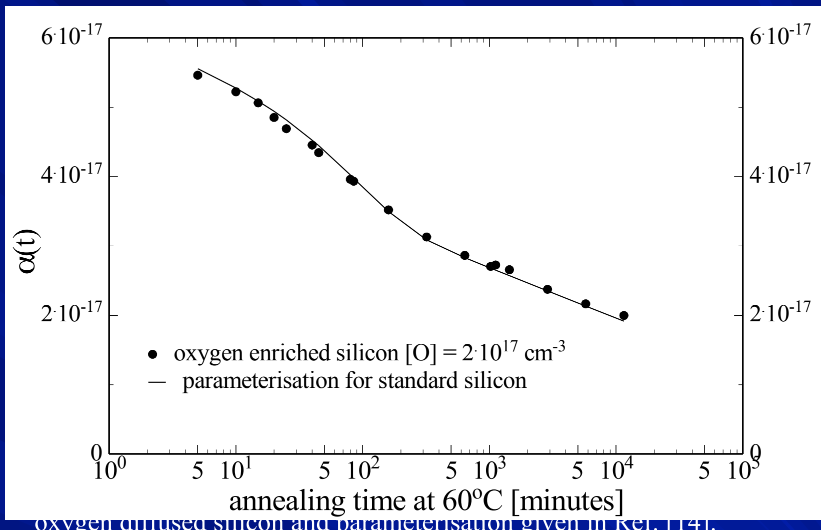
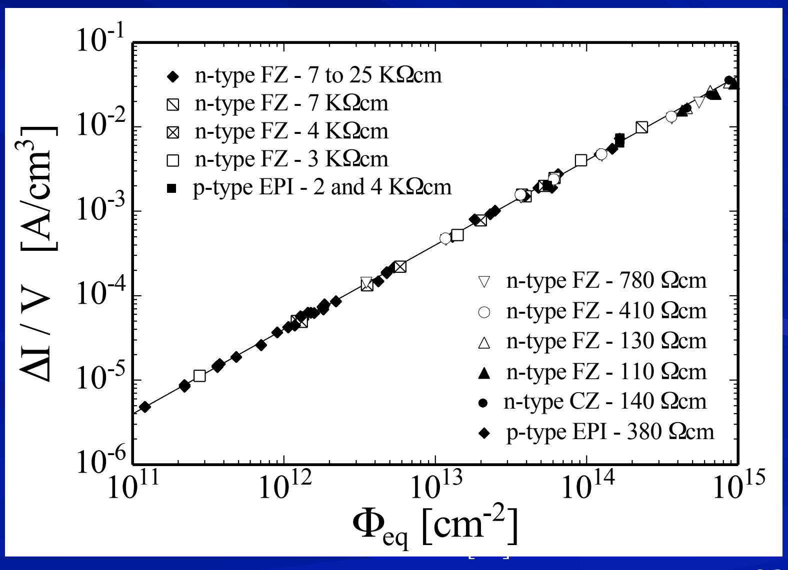
Leakage Current

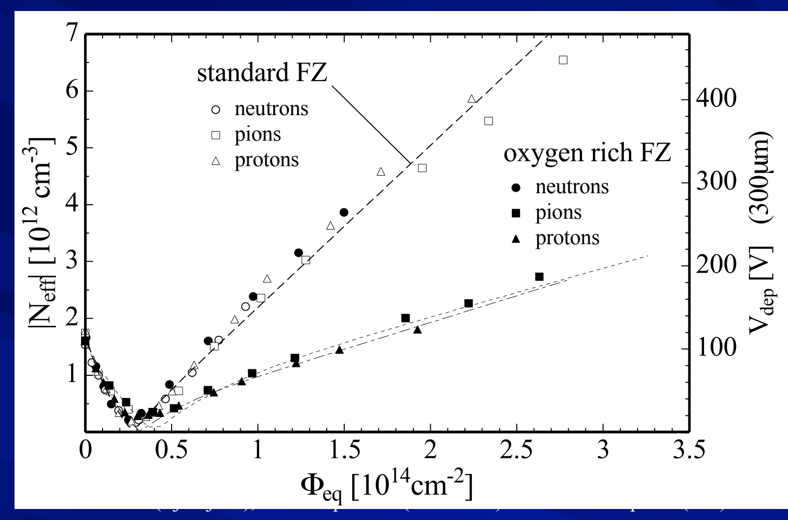
- Measured values of $\alpha(t)$
  - One quotes measured values of $\alpha(t)$ after complete annealing at T=20ºC: $\alpha_{\infty} = \alpha(t=\infty)$
  - 'World averages' for α_{∞} are :
    - 2.2 x 10^{-17} A/cm^3 for protons, pions
    - 2.9 x 10^{-17} A/cm^3 for neutrons
  - Recent results show α(t=80min,T=60ºC)= 4.0 x 10^{-17} A/cm^3 for all types of silicon, levels of impurities, and incident particle types (NIM A426 (1999)86).

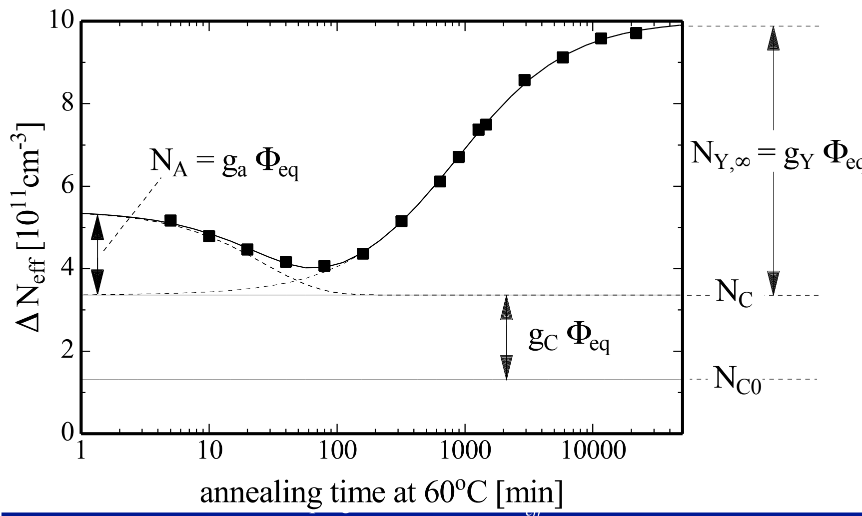


oxygen diffused silicon and parameterisation given in Ref. [14].



Depletion Voltage





Depletion voltage is often parameterized in three parts (Hamburg model):

$\Delta N_{eff}(T,t,\Phi) = N_A + N_C + N_Y$

- Short term annealing (N_A)

  $N_A = \Phi_{eq}\sum_i g_{a,i}\exp(-k_{a,i}(T)t)$
  - Reduces N_Y (beneficial)
  - Time constant is a few days at 20 C
- Stable component (N_c)

  $N_c = N_{c0}(1-\exp(-c\Phi_{eq}))+g_c\Phi_{eq}$
  - Does not anneal
  - Partial donor removal (exponential)
  - Creation of acceptor sites (linear)
- Long term reverse annealing (N_Y)

  $N_Y = N_{Y,\infty}[1-1/(1+ N_{Y,\infty}k_Y(T)t)]$, $N_{Y,\infty}= g_Y\Phi_{eq}$
  - Strong temperature dependence
  - 1 year at T=20 C or ~100 years at T= -7 C (LHC)
  - Must cool Si at the LHC

Most common semiconductors

- **Germanium:**
  - Used in nuclear physics
  - Needs cooling due to small band gap of 0.66 eV (usually done with liquid nitrogen at 77 K)
- **Silicon:**
  - Can be operated at room temperature (but electronics requires cooling)
  - Synergies with micro electronics industry
  - Standard material for vertex and tracking detectors in high energy physics
- **Diamond (CVD or single crystal):**
  - Large band gap (requires no depletion zone)
  - very radiation hard
  - Disadvantages: low signal and high cost

Compound semiconductors

- **Compound semiconductors consist of**
  - two (binary semiconductors) or
  - more than two atomic elements of the periodic table.
    - IV-IV- (e.g. *SiGe*, *SiC*),
    - II-V- (e.g. *GaAs*)
    - II-VI compounds (*CdTe, ZnSe*)
- **Important III-V compounds:**
  - ***GaAs***: Faster and probably more radiation resistant than Si. Drawback is less experience in industry and higher costs.
  - GaP, GaSb, InP, InAs, InSb, InAlP
- **important II-VI compounds:**
  - ***CdTe***: High atomic numbers (48+52) hence very efficient to detect photons.
  - ZnS, ZnSe, ZnTe, CdS, CdSe, Cd1-xZnxTe, Cd1-xZnxSe
