Abstract. Several recent results from the ATLAS experiment at the Large Hadron Collider are presented, using proton-proton collisions at $\sqrt{s} = 7$ TeV. Measurements of W bosons in association with b -jets and single c -quark jets are presented, in addition to a new measurement of the production of b -jets in association with Z bosons. These measurements allow QCD predictions to be tested and also probe the parton density of the proton. The associated production of quarkonia and vector bosons is observed in the $J/\psi + W$ channel, and compared to colour singlet and colour octet production models.

1. Introduction

The production of heavy quarks in conjunction with vector bosons at hadron colliders allows the validity of quantum chromodynamics (QCD) predictions and calculations to be tested. Understanding such processes is vital in the measurement of Higgs boson decays and in searches for physics beyond the Standard Model. Vector bosons produced with bottom or charm quarks give a unique sensitivity to the heavy quark density of the proton, while the associated production of vector bosons with quarkonium states (e.g. J/ψ) can provide insight into the quarkonium production mechanism in a new environment.

All the analyses presented here are based on the data recorded in the ATLAS detector [1] at the LHC in 2011 at $\sqrt{s} = 7$ TeV, with an integrated luminosity of 4.6 fb^{-1} . Samples of W or Z bosons are selected in their muon or electron final states, which give clean signatures for triggering and lepton identification. Events including Z bosons are identified using pairs of oppositely charged leptons, close to the expected Z mass, while W identification uses the missing transverse energy as a signature. The leptons are required to be isolated, to reduce multi-jet backgrounds, using either tracking or calorimeter information around the lepton.

2. W boson production in association with b -jets

The cross-section for W boson production in association with b -quark jets has been measured for one-jet and two-jet final states [2]. This channel is an important background for the Higgs production process $WH(\rightarrow b\bar{b})$. The b -jet contribution is extracted from a template fit to weights from a b -tagging algorithm, and corrected for backgrounds and detector effects. Figure 1 shows the fiducial $W+b$ -jets cross-sections, which are compared with next-to-leading order predictions from MCFM [3] and POWHEG [4], and leading-order ALPGEN [5] predictions. The one-jet data lie slightly above the predictions, but are consistent within 1.5σ , while the two-jet measurements agree well with the predictions. Differential cross-sections as a function of the leading b -jet p_T show that the predictions underestimate the one-jet data slightly at high p_T .

3. W boson production in association with charm

The production of a W boson in association with a single charm quark has also been studied [6]. To leading order, this process is dominated by the gs and $g\bar{s}$ production channels, at the level of 90%, and is therefore an excellent probe of the s -quark distribution function in the proton. Previous analyses have shown a preference for s -quark suppression relative to d -quarks in the sea; however, a recent analysis of ATLAS W and Z production and HERA DIS data [7] favoured a flavour-symmetric sea at LHC scales and $x \sim 0.01$. The W +charm data allow these properties to be tested further.

Charm quarks are tagged either using charmed hadrons in the decay modes $D^+ \rightarrow K^+\pi^+\pi^+$ and $D^{*+} \rightarrow D^0\pi^+$ (and charge conjugates), or requiring a particle jet containing a soft semileptonic decay to a muon. For the signal process, the charges of the W boson and the charm quark are expected to be opposite in sign. Since most background processes are charge-symmetric, for example $W+b\bar{b}$ or $W+c\bar{c}$, signal distributions can be extracted by subtracting same-sign from opposite-sign distributions.

The W +charm cross-sections are measured within fiducial phase space regions, and are compared with predictions from the next-to-leading order aMC@NLO [8] in combination with HERWIG++ [9] and a number of different PDF sets. These NLO and NNLO PDF sets give rise to variations of approximately 25% in the predicted cross-sections. The uncertainties on the data cover a wide range of predictions, but tend to disfavour those which have a suppressed s -quark component (MSTW2008, NNPDF2.3 and HERAPDF1.5), as shown in Figure 2 for the $W^+ + \bar{c}$ -jet cross-section. The ratio of the s -to- d sea-quark distributions is evaluated in the context of HERAPDF1.5 as $0.96^{+0.26}_{-0.30}$ at $Q^2 = 1.9 \text{ GeV}^2$. This is consistent with an SU(3)-symmetric light-quark sea. The ratio of cross-sections $(W^+ + \bar{c})/(W^- + c)$ is consistent within uncertainties with PDFs including a small $s:\bar{s}$ asymmetry and no asymmetry.

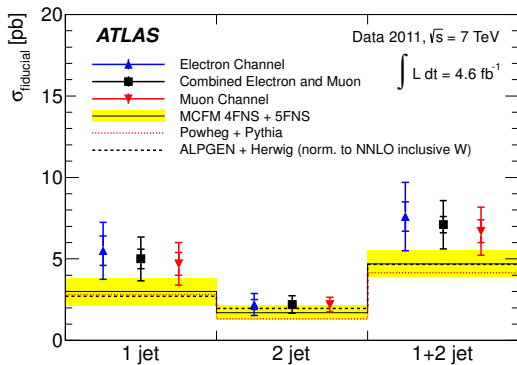

Figure 1. W + b -jet cross-sections in the 1-jet, 2-jet, and 1+2-jet fiducial regions [2].

Figure 2. Measured $W^+ + \bar{c}$ -jet fiducial cross-section compared to various PDF predictions based on aMC@NLO [6].

4. Z boson production in association with b -jets

A recent analysis of the production of Z bosons in association with b -jets [10] allows several aspects of QCD predictions to be tested. For example, the four- and five-flavour number schemes (4FNS, 5FNS) can be compared, where the 5FNS includes b -quark density in the proton, as can predictions involving massive or massless b -quarks, or calculations to different orders. The b -jets are identified using template fits to appropriate b -tagging variables in either the one- b -tag or two- b -tag cases, then yields and differential distributions are corrected for reconstruction efficiencies and detector resolution effects.

Cross-sections for $Z+\geq 1b$ -jet and $Z+\geq 2b$ -jets are compared with various predictions, as shown in Figure 3 for the 1- b -jet case. Firstly, the data are compared with MCFM [3], an NLO prediction in the 5FNS, evaluated for several different PDF sets. All the MCFM predictions agree with the data within uncertainties. Two different predictions from aMC@NLO [8] plus HERWIG++ [9] are also considered. One is a $Z+b$ calculation in the 5FNS and the other is $Z+b\bar{b}$ in the 4FNS. In the 1- b -jet case, both calculations are next-to-leading order and the dominant difference is the number of flavours; the data prefer the 5FNS. For 2- b -jets, the $Z+b$ 5FNS calculation is now a leading-order approximation and does not describe the data so well (in contrast to the NLO 4FNS). Leading-order predictions from ALPGEN [5] and SHERPA [11] are also shown. These underestimate the data, but do not include the theoretical uncertainties. Twelve differential cross-section distributions are measured, allowing more stringent tests of the theoretical predictions. For example, the 2- b -jet cross-section as a function of the opening angle between the b jets (Figure 4) shows some discrepancies between data and predictions at small angles.

Figure 3. Cross-section for $Z+\geq 1b$ -jet and comparison with theoretical predictions [10].

Figure 4. The cross-section for $Z+\geq 2b$ -jets as a function of the opening angle $\Delta R(b, b)$ [10].

5. W boson production with prompt J/ψ mesons

An alternative measurement, which looks for quarkonium formation instead of b - or c -jets, is the associated production of W bosons with prompt J/ψ [12], where the J/ψ and W boson are both identified in their muon decay modes. The measurement probes the quarkonium production mechanism and the possible contributions from colour singlet and colour octet processes. This signature will also be sensitive to multiple parton interactions, in which the W and J/ψ are produced by two pairs of partons from the same proton-proton collision, and the current measurement includes an estimate of the double parton scattering (DPS) contribution.

As with many J/ψ analyses, the invariant mass and pseudo-proper time are fitted simultaneously to extract the prompt J/ψ component. Each prompt candidate then receives a weight in the W transverse mass distribution, which is fitted with W and multi-jet templates, to estimate a multi-jet contamination of 0.1 ± 4.6 events. The associated prompt J/ψ plus W signal is ~ 27 events, which is incompatible with the background-only hypothesis at 5.1σ , and is the first observation of this process.

The cross-section of $W+J/\psi$ is measured relative to the inclusive W cross-section in the same dataset. The contribution from DPS is estimated under the assumption that the W and J/ψ contributions are independent and uncorrelated, and are scaled by the effective cross-section obtained from $W+2$ -jet events at ATLAS [13]: its magnitude is $\sim 40\%$ of the total. The azimuthal angle between the W and the J/ψ

will be uniform for independent DPS processes but will peak at $\sim \pi$ for single scattering (SPS) events. The data appear to show both components, as expected, and the differential cross-section as a function of p_T (Figure 5) indicates that SPS dominates at low p_T of the J/ψ . The cross-section ratio is corrected for J/ψ acceptance and DPS, then the resulting SPS cross-section is compared with predictions from two models: a LO colour singlet model [14] and NLO colour octet model [15]. The theoretical predictions lie below the data, but both are within 2σ of the large experimental uncertainties, as shown in Figure 6.

Figure 5. The W +prompt J/ψ to inclusive W production cross-section ratio as a function of J/ψ p_T [12].

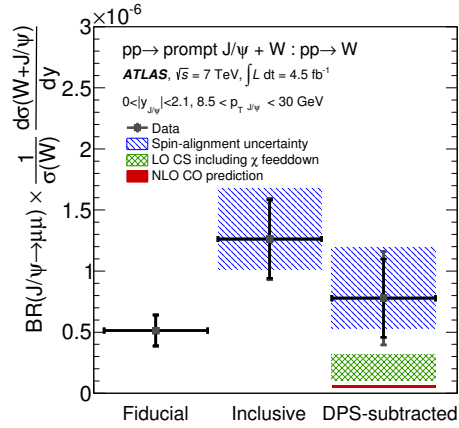

Figure 6. The W +prompt J/ψ to inclusive W production cross-section ratio [12].

6. Summary

Recent measurements of heavy flavour and vector boson production in ATLAS have been presented. These allow more stringent tests of QCD predictions in a new regime: measurements with b - or c -jets give access to the proton structure function and heavy flavour densities, while measurements of quarkonium with vector bosons open a new field in understanding both quarkonium production and multiple parton interactions.
