Lecture 2: Magnets & training, plus fine filaments

Magnets

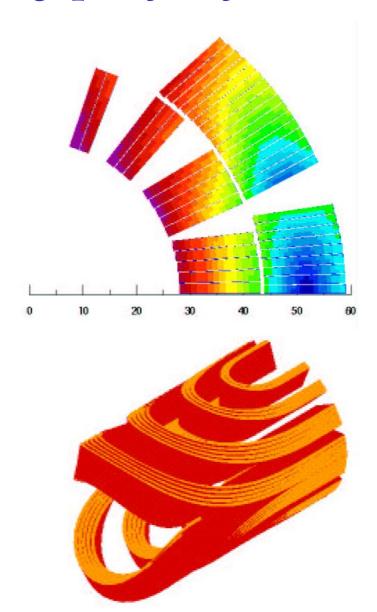

- magnetic fields above 2 Tesla
- coil shapes for solenoids, dipoles and quadrupoles
- engineering current density
- load lines

Degradation & Training

- causes of training release of energy within the magnet
- reducing training stability and minimum quench energy MQE
- need copper and fine filaments for low MQE

Flux Jumping

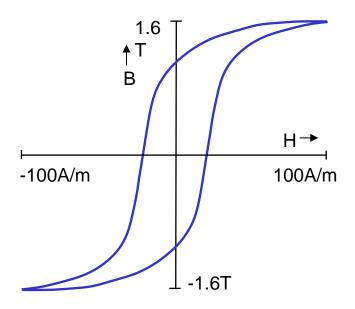

need for fine filaments

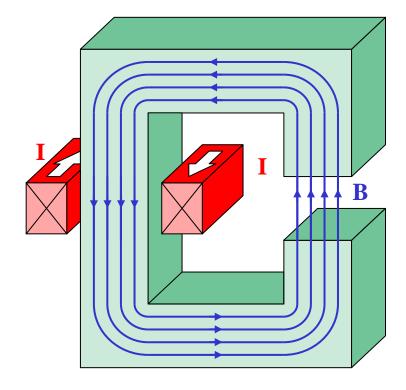

Martin Wilson Lecture 2 slide1 JUAS February 2013

Fields and ways to create them: conventional

- conventional electromagnets have an iron yoke
 - reduces magnetic reluctance
 - reduces ampere turns required
 - reduces power consumption
- iron guides and shapes the field

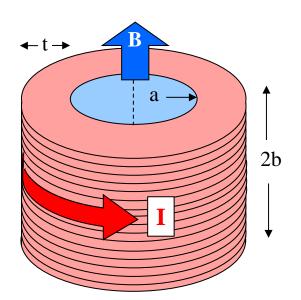

BUT iron saturates at ~ 2T

Iron electromagnet

– for accelerators, motors,
transformers, generators etc

for higher fields we cannot rely on iron field must be created and shaped by the winding

Solenoids

- no iron field shape depends only on the winding
- azimuthal current flow, eg wire wound on bobbin, axial field
- the field produced by an infinitely long solenoid is

$$B = \mu_o NI = \mu_o J_e t$$

where N = number of turns/unitlength, I = current,

 J_e = engineering current density

- so high $J_e \Longrightarrow$ thin compact economical winding
- in solenoids of finite length the central field is

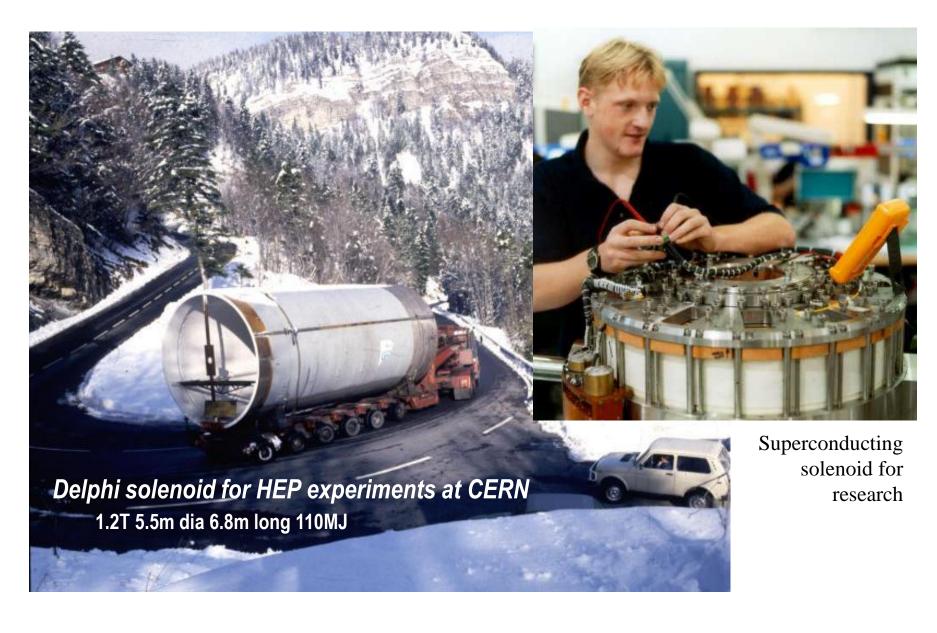

$$B = \mu_o J_e t f(\beta, \tau)$$

where
$$\beta = b/a$$
 $\tau = t/a$

• field uniformity and the ratio of peak field to central field get worse in short fat solenoids

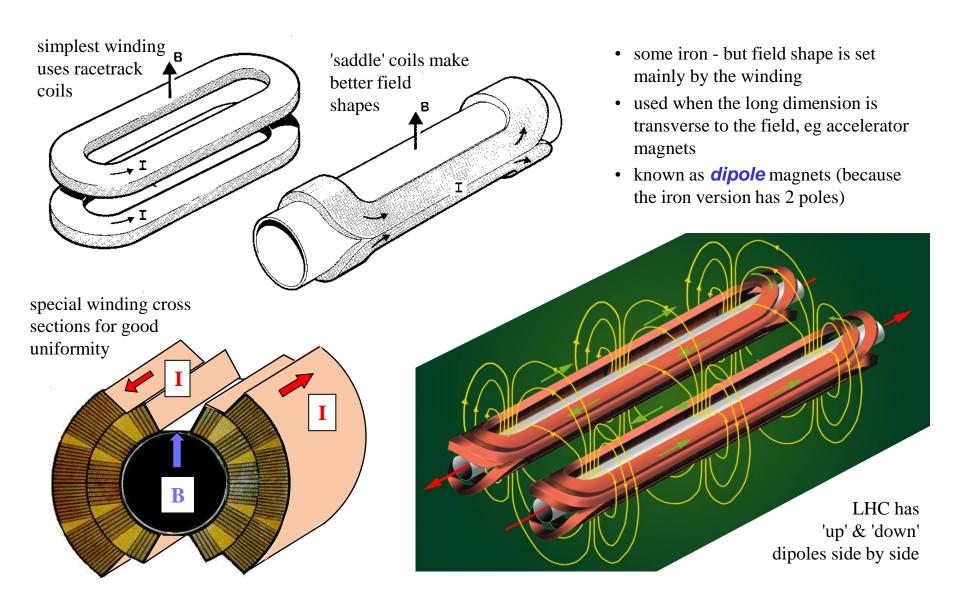

Superconducting solenoids

Martin Wilson Lecture 2 slide4

JUAS February 2013

Accelerators need transverse fields

Martin Wilson Lecture 2 slide5

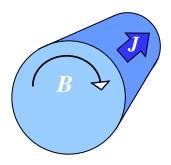

JUAS February 2013

Dipole field from overlapping cylinders

Ampere's law for the field inside a cylinder carrying uniform current density

$$\oint B.ds = 2\pi rB = \mu_o I = \mu_o \pi r^2 J$$

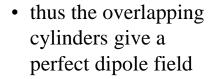

$$B = \frac{\mu_o J r}{2}$$

- two cylinders with opposite currents
- push them together
- currents cancel where they overlap \Rightarrow aperture
- fields in the aperture:

$$B_y = \frac{\mu_o J}{2} \left(-r_1 cos\theta_1 + r_2 cos\theta_2 \right) = \frac{-\mu_o J t}{2}$$

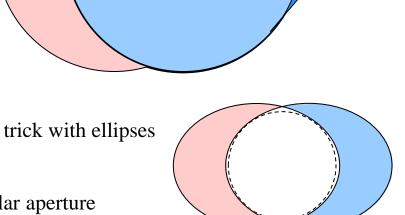

$$B_x = \frac{\mu_o J}{2} \left(-r_1 sin\theta_1 + r_2 sin\theta_2 \right) = 0$$

$$B_{y} = \frac{-\mu_{o} J_{e} t}{2}$$

Windings of distributed current density

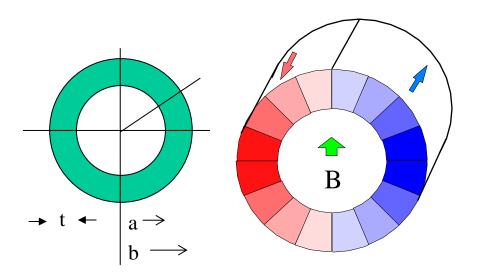

Analyse thin current sheets flowing on the surface of a cylinder using complex algebra. Let the **linear** current density (Amps per m of circumference) be $g_n = g_o \cos(n\theta)$ (Am⁻¹)

For n = 1 we find a pure dipole field inside the cylinder, n = 2 gives a quadrupole etc.

Now superpose many cylinders of increasing radius to get a thick walled cylinder carrying an (area) current density (Am^{-2}) $J_n = J_o \cos(n\theta)$

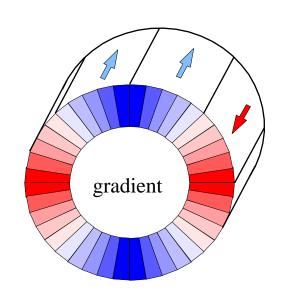

$$n=1 J_{1}(\theta) = J_{0} \cos \theta$$

$$B_x = 0$$
 $B_y = -\mu_o J_0 (b-a)/2 = -\mu_o J_0 t/2$

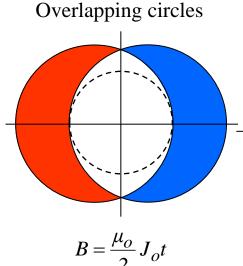

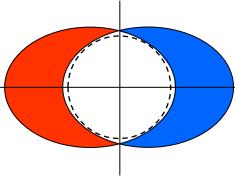

$$n=2 J_{2}(\theta) = J_{0} \cos 2\theta$$

$$B_x = \frac{\mu_o J_0}{2} y \ln \left(\frac{b}{a}\right) \qquad B_y = \frac{\mu_o J_0}{2} x \ln \left(\frac{b}{a}\right)$$

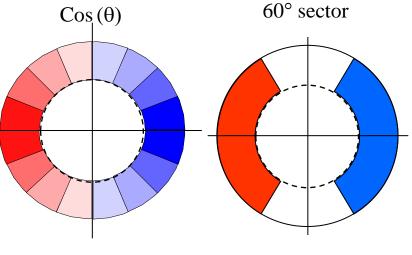

Summary of simplified dipole windings

Overlapping ellipses

 $t = winding thickness J_o = engineering current density$

where $\alpha = c/(b+c)$ c = height of ellipse

b = width

 $B = \mu_o J_o t \alpha$

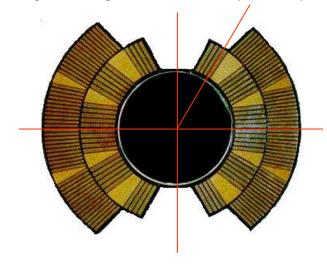

best estimate of forces

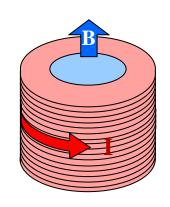

$$B = \frac{2\mu_o}{\pi} J_o t \sin(60^o)$$

$$\frac{2}{\pi}$$
Sin(60°) = 0.55

best estimate of peak field

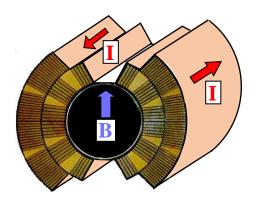

LHC dipole winding

recap solenoid

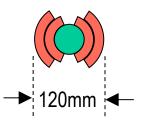

$$B = \mu_o J_e t f(\beta, \tau)$$

Importance of (engineering) current density in dipoles

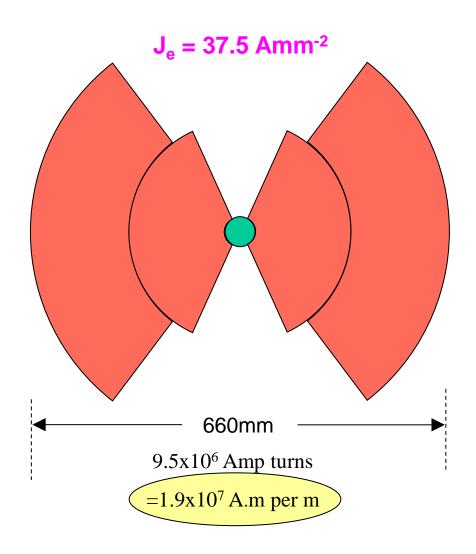

LHC dipole

 $J_e = 375 \text{ Amm}^{-2}$

9.5x10⁵ Amp turns

 $=1.9 \times 10^6 \text{ A.m per m}$

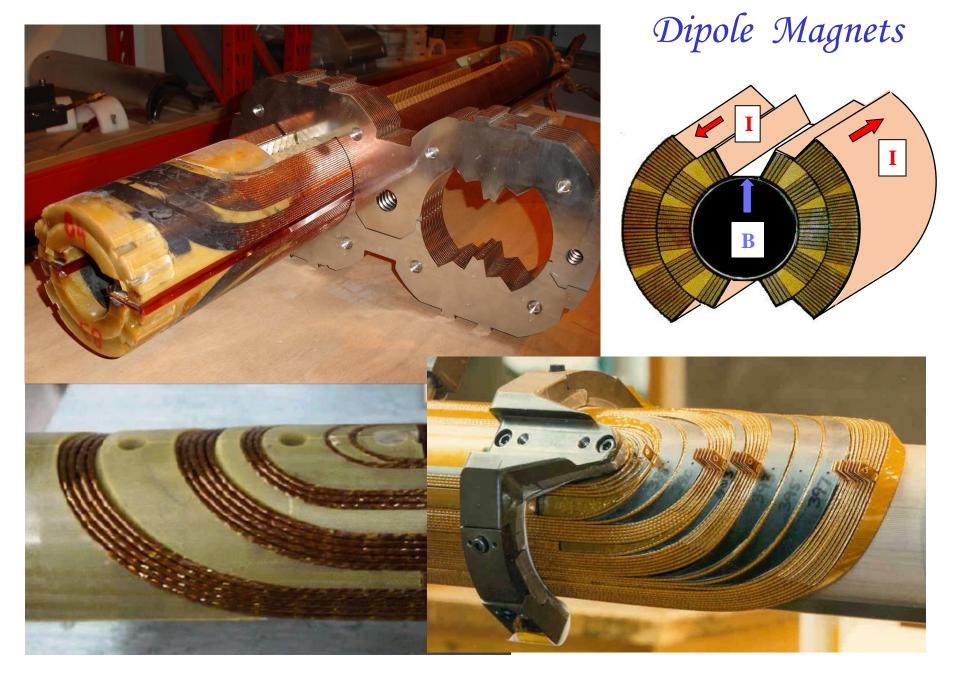

by a perfect dipole is

$$B = \mu_o J_e \frac{t}{2}$$

Martin Wilson Lecture 2 slide9

JUAS February 2013

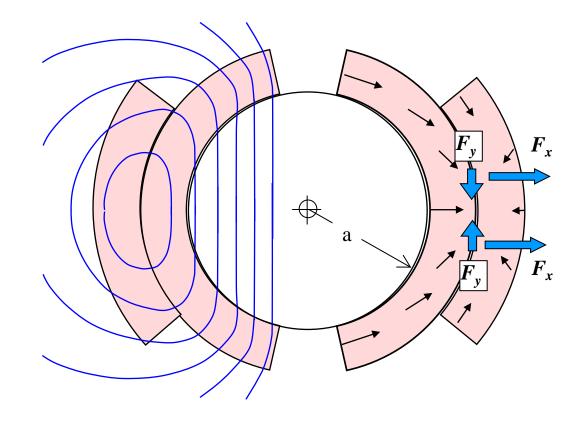

Martin Wilson Lecture 2 slide10

JUAS February 2013

Electromagnetic forces in dipoles

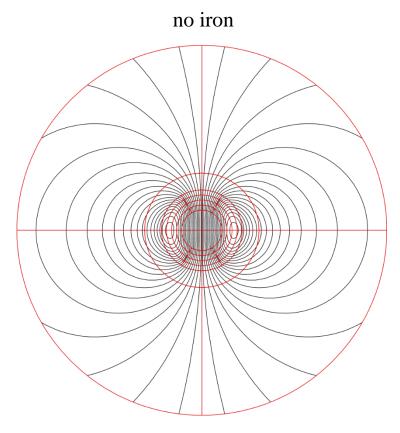

- forces in a dipole are horizontally outwards and vertically towards the median plane
- unlike a solenoid, the bursting forces cannot be supported by tension in the winding
- the outward force must be supported by an external structure
- both forces cause compressive stress and shear in the conductor and insulation
- apart from the ends, there is no tension in the conductor
- simple analysis for thin windings

$$F_x = \frac{B_i^2}{2\mu_o} \frac{4a}{3}$$

$$F_y = -\frac{B_i^2}{2\mu_o} \frac{4a}{3}$$

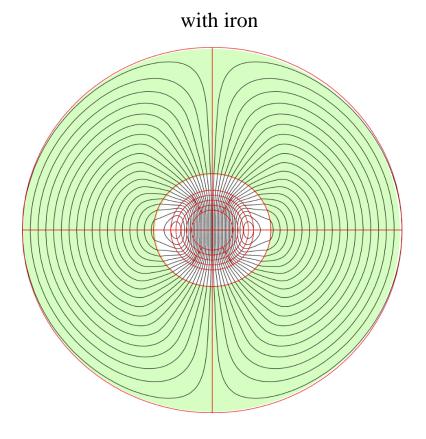

Estimating the iron shield thickness

some flux returns close to the coil flux through ½ coil aperture

$$\phi_c = B_o a$$

a = coil radius

almost all flux returns through the iron return flux through iron (one side)

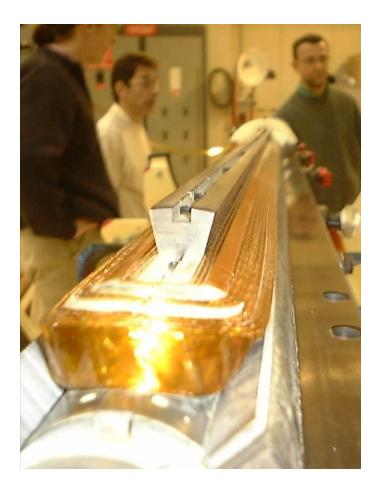

$$\phi_i = B_{sat} t$$

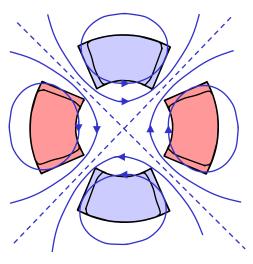

t = iron thickness

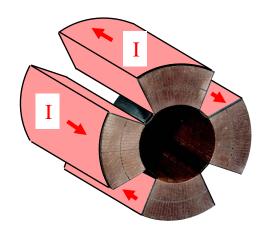

$$\phi_i \sim \phi_c$$

$$t \sim a B_o / B_{sat}$$

Quadrupole windings

 $B_x = ky$ $B_y = kx$

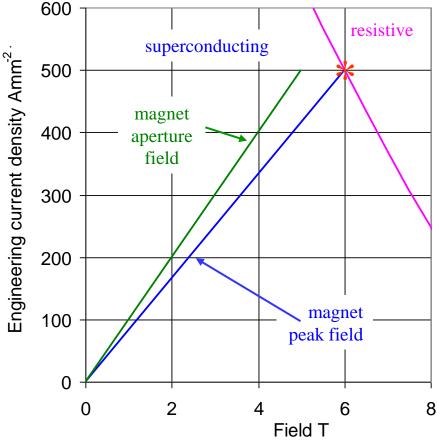

Martin Wilson Lecture 2 slide13

JUAS February 2013

Critical surface and magnet load lines

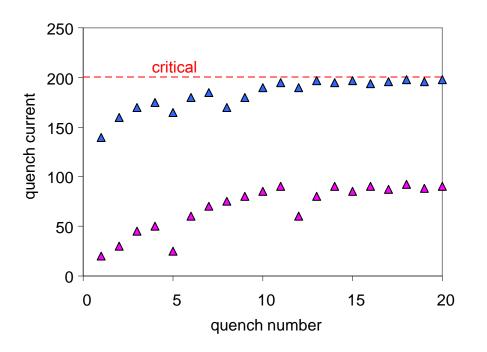

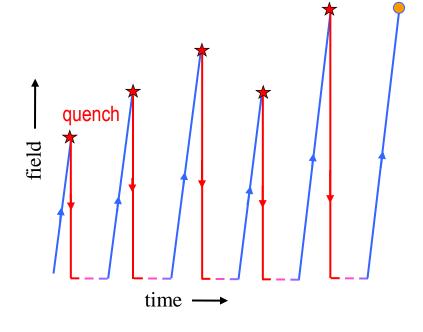

- load line relates magnet field to current
- peak field > aperture (useful) field
- we expect the magnet to go resistive 'quench' where the peak field load line crosses the critical current line *

Martin Wilson Lecture 2 slide14 JUAS February 2013

Degraded performance and 'training' of magnets

- early disappointment for magnet makers when they ramped up the magnet current for the first time
- instead of going up to the critical line, it 'quenched' (went resistive) at less than the expected current
- at the next try it did better
- known as *training*

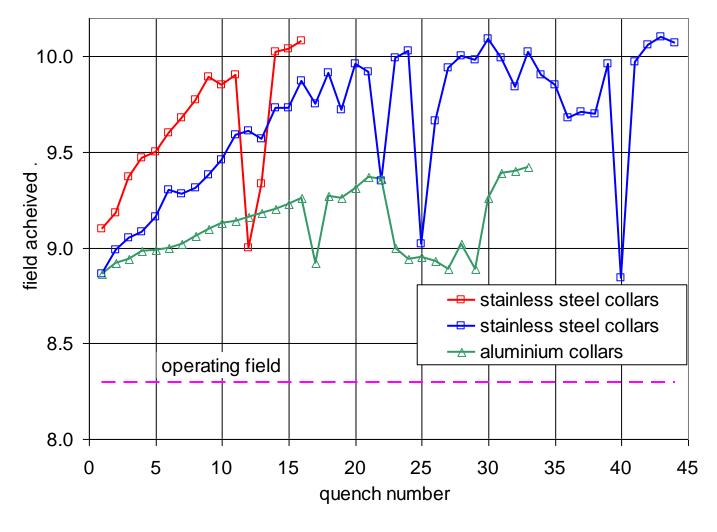

- after a *quench*, the stored energy of the magnet is dissipated in the magnet, raising its temperature way above critical
- you must wait for it to cool down and then try again
- well made magnets ▲ are better than poorly made ▲

Martin Wilson Lecture 2 slide15

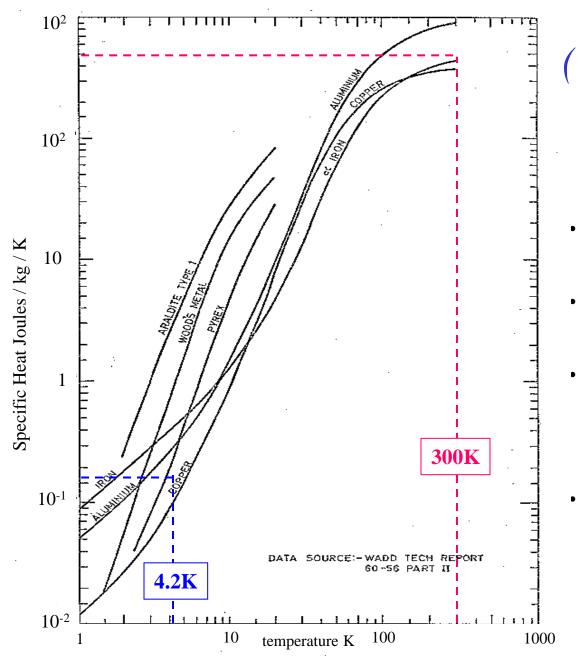

JUAS February 2013

'Training' of magnets

- it's better than the old days, but training is still with us
- it seems to be affected by the construction technique of the magnet
- it can be wiped out if the magnet is warmed to room temperature
- 'de-training is the most worrysome feature

Training of LHC short prototype dipoles (from A. Siemko)

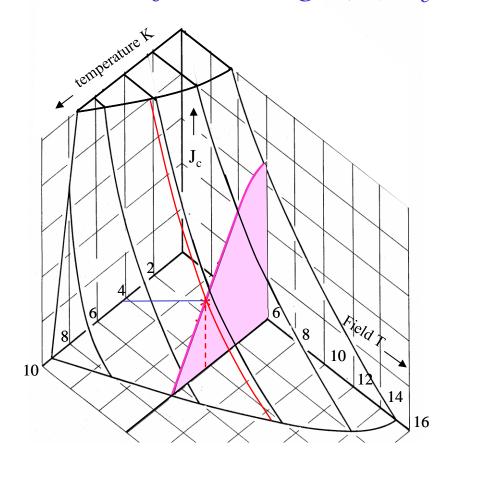

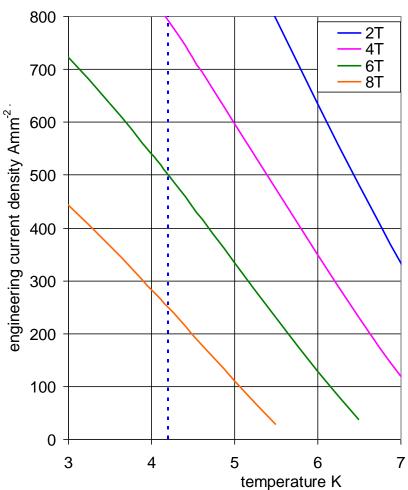

Causes of training: (1) low specific heat

- the specific heat of all substances falls with temperature
- at 4.2K, it is ~2,000 times less than at room temperature
- a given release of energy within the winding thus produce a temperature rise 2,000 times greater than at room temperature
- the smallest energy release can therefore produce catastrophic effects

Martin Wilson Lecture 2 slide17 JUAS February 2013

Causes of training: (2) J_c decreases with temperature

at any field, J_c of NbTi falls ~ linearly with temperature

- so any temperature rise drives the conductor towards the resistive state

Causes of training: (3) conductor motion

Conductors in a magnet are pushed by the electromagnetic forces. Sometimes they move suddenly under this force - the magnet 'creaks' as the stress comes on. A large fraction of the work done by the magnetic field in pushing the conductor is released as frictional heating

work done per unit length of conductor if it is pushed a distance δz

$$W = F.\delta z = B.I.\delta z$$

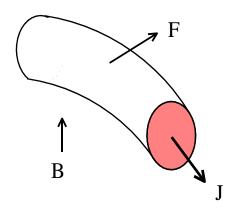

$$Q = B.J. \delta z$$

typical numbers for NbTi:

$$B = 5T \quad J_{eng} = 5 \text{ x } 10^8 \text{ A.m}^{-2}$$
 so if $\delta = 10 \text{ }\mu\text{m}$ then Q = 2.5 x 10^4 J.m^{-3}

Starting from 4.2K $\theta_{final} = 7.5$ K

can **YOU**engineer a
winding to
better than

10 μm?

Martin Wilson Lecture 2 slide19 JUAS February 2013

Causes of training: (4) resin cracking

Try to stop wire movement by impregnating the winding with epoxy resin. But resin contracts more than metal, so it goes into tension. Almost all organic materials become brittle at low temperature.

brittleness + tension \Rightarrow cracking \Rightarrow energy release

Calculate strain energy in resin caused by differential thermal contraction

 σ = tensile stress Y = Young's modulus v = Poisson's ratio

 ε = differential strain due to cooling = contraction (resin - metal)

typically:
$$\varepsilon = (11.5 - 3) \times 10^{-3}$$
 $Y = 7 \times 10^{9} \text{ Pa}$ $v = \frac{1}{3}$

uniaxial strain
$$Q_1 = \frac{\sigma^2}{2Y} = \frac{Y\varepsilon^2}{2}$$
 $Q_1 = 2.5 \times 10^5 \text{ J.m}^{-3}$ $\theta_{final} = 16\text{K}$

$$Q_3 = \frac{3\sigma^2(1-2\nu)}{2Y} = \frac{3Y\varepsilon^2}{2(1-2\nu)}$$
 $Q_3 = 2.3 \times 10^6 \text{ J.m}^{-3}$ $\theta_{final} = 28\text{K}$

$$Q_3 = 2.3 \times 10^6 \, \text{J.m}^{-3}$$

$$\theta_{final} = 28$$
K

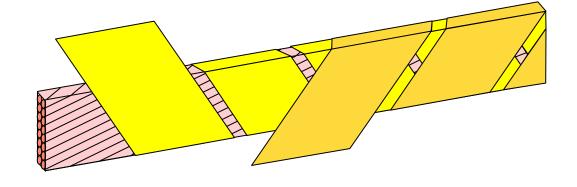

Interesting fact: magnets impregnated with paraffin wax show almost no training although the wax is full of cracks after cooldown.

Presumably the wax breaks at low or before it has had chance to store up any strain energy

How to reduce training?

1) Reduce the disturbances occurring in the magnet winding

- make the winding fit together exactly to reduce movement of conductors under field forces
- pre-compress the winding to reduce movement under field forces
- if using resin, minimize the volume and choose a crack resistant type
- match thermal contractions, eg fill epoxy with mineral or glass fibre
- impregnate with wax but poor mechanical properties
- most accelerator magnets are insulated using a Kapton film with a very thin adhesive coating on the outer face
 - away from the superconductor
- allows liquid helium to penetrate the cable

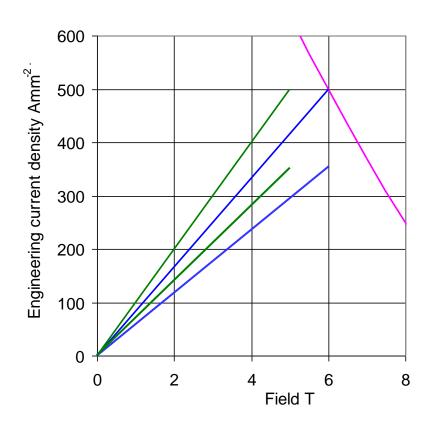

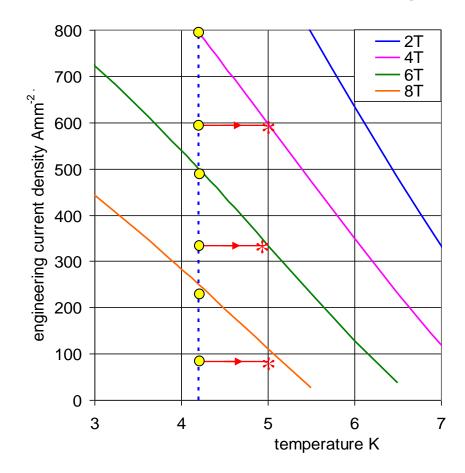

Martin Wilson Lecture 2 slide21 JUAS February 2013

How to reduce training?

2) Make the conductor able to withstand disturbances without quenching

- increase the temperature margin ~ 0.8 K
- operate at lower current
- but need more winding to make same field

- harder at high fields than at low fields
- higher critical temperature HTS?

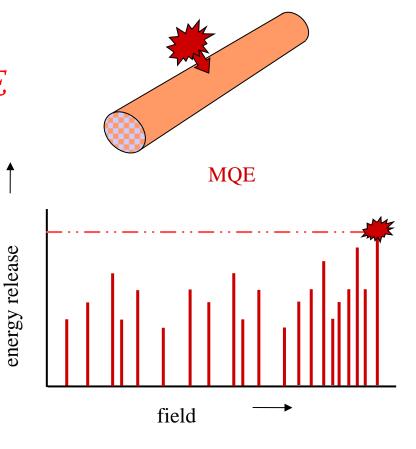

How to reduce training?

2) Make the conductor able to withstand disturbances without quenching

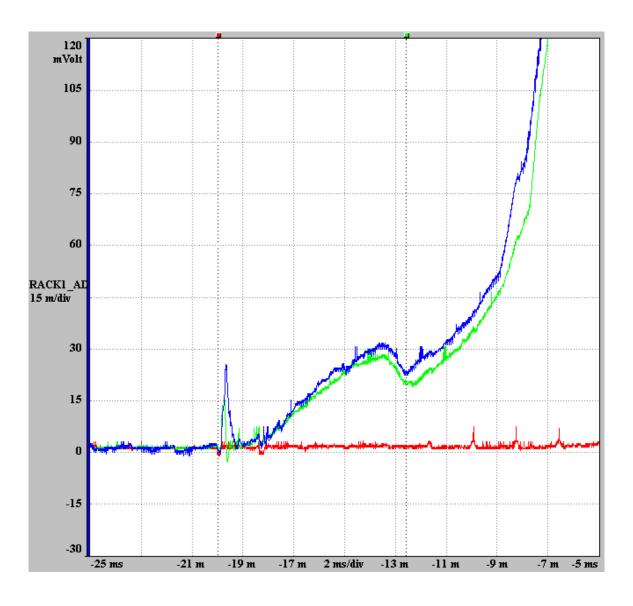

- increase the temperature margin
- increase the cooling more cooled surface better heat transfer superfluid helium
- increase the specific heat experiments with Gd₂O₂S HoCu₂ etc
- most of this may be characterized by a single number

Minimum Quench Energy MQE

- defined as the energy input at a point in very short time which is just enough to trigger a quench.
- energy input > MQE \Rightarrow quench
- energy input < MQE \Rightarrow recovery
- energy disturbances occur at random as a magnet is ramped up to field
- for good magnet performance we want a high MQE

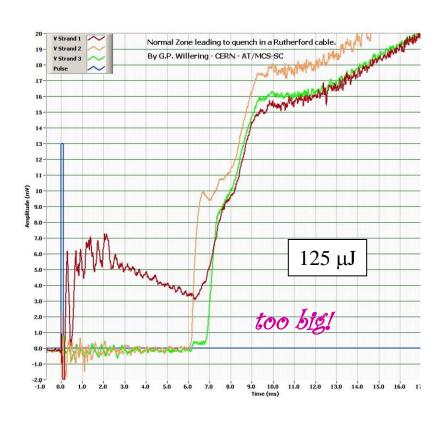

Quench initiation by a disturbance

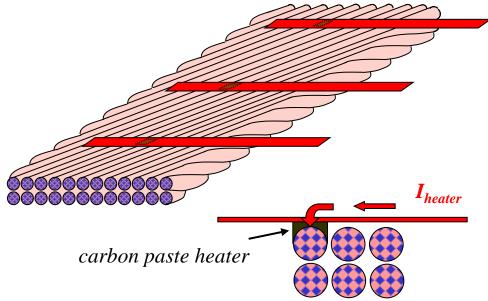

- CERN picture of the internal voltage in an LHC dipole just before a quench
- note the initiating spike conductor motion?
- after the spike, conductor goes resistive, then it almost recovers
- but then goes on to a full quench
- this disturbance was more than the MQE

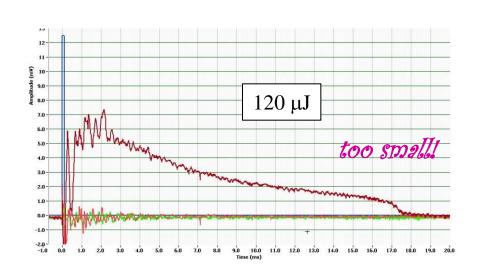

Martin Wilson Lecture 2 slide24 JUAS February 2013

Measuring the MQE for a cable

- pass a small pulse of current from the copper foil to the superconducting wire
- generates heat in the carbon paste contact
- how much to quench the cable?
- find the Minimum Quench Energy MQE

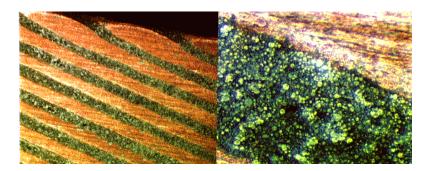

Martin Wilson Lecture 2 slide25 JUAS February 2013

Different cables have different MQEs

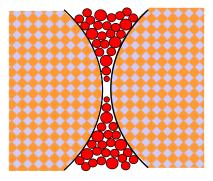

- similar cables with different cooling
- better cooling gives higher MQE
- high MQE is best because it is harder to quench the magnet

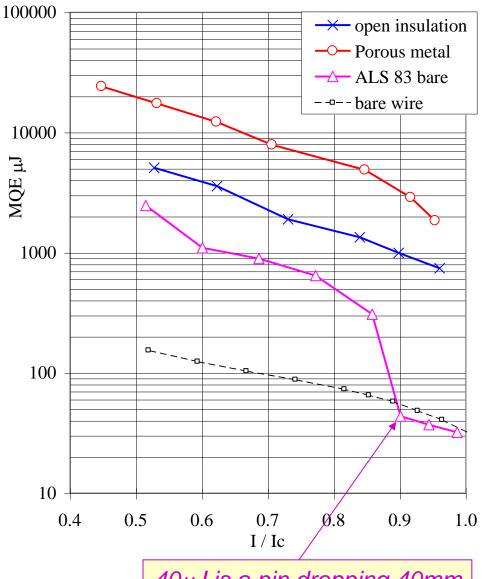

• experimental cable with porous metal

heat exchanger

 excellent heat transfer to the liquid helium coolant

 $40\mu J$ is a pin dropping 40mm

Factors affecting the Minimum Quench Energy

- heat a short zone of conductor \Rightarrow resistive
- heat conducted out > generation ⇒ zone shrinks
- heat conducted out < generation ⇒ zone grows
- boundary between the two conditions is the minimum propagating zone MPZ
- large MPZ ⇒ stability against disturbances

Very approximate heat balance

$$\frac{2kA(\theta_c - \theta_o)}{l} + hPl(\theta_c - \theta_o) = J_c^2 \rho Al$$

so length of MPZ
$$l = \left\{ \frac{2k(\theta_c - \theta_o)}{J_c^2 \rho - \frac{hP}{A}(\theta_c - \theta_o)} \right\}^{\frac{1}{2}}$$

where: k = thermal conductivity $\rho = \text{resistivity}$

A =cross sectional area of conductor

h = heat transfer coefficient to coolant - if there is any in contact

P =cooled perimeter of conductor

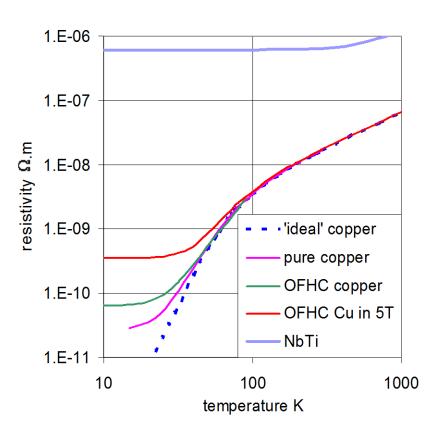

Energy to set up MPZ is the Minimum Quench Energy

 $long MPZ \Rightarrow large MQE$

How to make a long $MPZ \Rightarrow large MQE$

$$l = \left\{ \frac{2k(\theta_c - \theta_o)}{J_c^2 \rho - \frac{hP}{A}(\theta_c - \theta_o)} \right\}^{\frac{1}{2}}$$

- make thermal conductivity *k* large
- make resistivity ρ small
- make heat transfer hP/A large (but \Rightarrow low J_{eng})

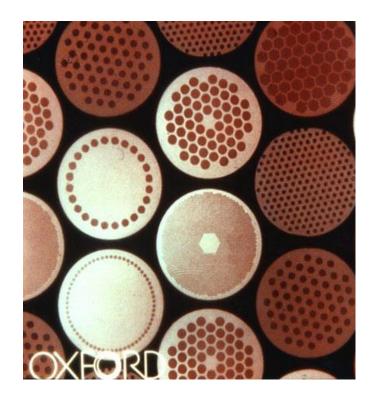

Large $MPZ \Rightarrow large MQE \Rightarrow less training$

$$l = \left\{ \frac{2k(\theta_c - \theta_o)}{J_c^2 \rho - \frac{hP}{A}(\theta_c - \theta_o)} \right\}^{\frac{1}{2}}$$
• make thermal conductivity k large
• make resistivity ρ small
• make heat transfer term hP/A large

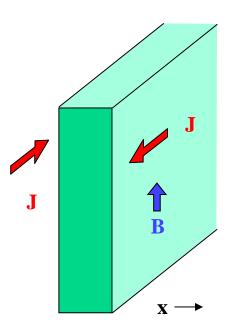

- make thermal conductivity *k* large

- NbTi has high ρ and low k
- copper has low ρ and high k
- mix copper and NbTi in a filamentary composite wire
- make NbTi in *fine filaments* for intimate mixing
- maximum diameter of filaments ~ 50μm
- make the windings porous to liquid helium - superfluid is best
- fine filaments also eliminate flux jumping (see later slides)

Another cause of training: flux jumping

- recap: changing magnetic fields induce screening currents in superconductors
- screening currents are in addition to transport currents, which come from the power supply
- like eddy currents but don't decay because no resistance,

- usual model is a superconducting slab in a changing magnetic field B_V
- assume it's infinitely long in the z and y directions simplifies to a 1 dim problem
- dB/dt induces an electric field E which causes screening currents to flow at critical current density J_c
- known as the critical state model or Bean model
- in the 1 dim infinite slab geometry, Maxwell's equation says

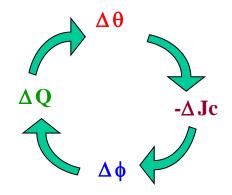

$$\frac{\partial B_{y}}{\partial x} = -\mu_{o} J_{z} = \mu_{o} J_{c}$$

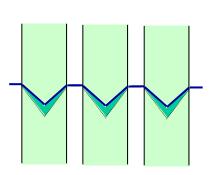

• so uniform J_c means a constant field gradient inside the superconductor

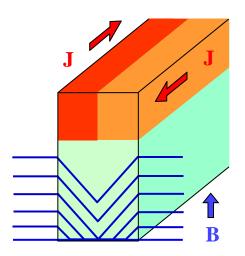

Flux Jumping

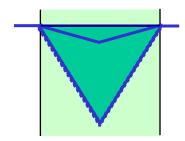

a magnetic thermal feedback instability

- screening currents
- temperature rise
- reduced critical current density
- flux motion
- energy dissipation
- temperature rise
- cure flux jumping by weakening a link in the feedback loop
- fine filaments reduce $\Delta \phi$ for a given $-\Delta Jc$
- for NbTi the stable diameter is ~ 50μm

Martin Wilson Lecture 2 slide31

JUAS February 2013

Flux jumping: the numbers for NbTi

criterion for stability against flux jumping a = half width offilament

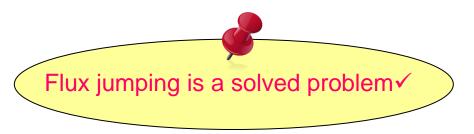

$$a = \frac{1}{J_c} \left\{ \frac{3\gamma \ C(\theta_c - \theta_o)}{\mu_o} \right\}^{\frac{1}{2}}$$

typical figures for NbTi at 4.2K and 1T J_c critical current density = 7.5 x 10 9 Am⁻² γ density = 6.2 x 10 3 kg.m³ C specific heat = 0.89 J.kg⁻¹K⁻¹ θ_c critical temperature = 9.0K

so $a = 33 \mu m$, ie 66 μ m diameter filaments

Notes:

- least stable at low field because J_c is highest
- instability gets worse with decreasing temperature because J_c increases and C decreases
- criterion gives the size at which filament is just stable against infinitely small disturbances
 still sensitive to moderate disturbances, eg mechanical movement
- better to go somewhat smaller than the limiting size
- in practice 50µm diameter seems to work OK

Concluding remarks

- superconducting magnets can make higher fields than conventional because they don't need iron which saturates at 2T although iron is often used for shielding
- to get different field shapes you have to shape the <u>winding</u> (not the iron)
- practical winding shapes are derived from the ideal overlapping ellipses or $J = J_o Cos \theta$
- engineering current density is important for a compact economic magnet design
- expected magnet performance is given by the intersection of the load line and critical surface
- degraded performance and training are still a problem for magnets and de-training is worse
- improve training by good winding construction
 - ⇒ no movement, low thermal contraction, no cracking
- improve training by making the conductor have a high MQE
 - temperature margin, high conductivity, good cooling
 - NbTi in good contact with copper ⇒ fine filaments
- changing fields induce screening currents in all superconductors ⇒ flux jumping
- flux jumping did cause degraded magnet performance but fine filaments have now cured it
