イロト イポト イヨト イヨト

- Inflation proposes to explain large scale homogeneity and flatness of the visible universe
- However most treatments of inflation assume homogeneity to begin with
- Lore: inflation can only begin if you initially assume homogeneity on Hubble scales
- Arguably no initial conditions problem if $V_{\text{Inflation}} \sim M_{Pl}$, however models with $V_{\text{Inflation}} \ll M_{Pl}$ popular, especially with new results from observations

Question to address: can we begin from very inhomogeneous conditions and eventually transition to exponential expansion?

イロト イポト イヨト イヨト

- Inflation is an attractor need to consider large/nonlinear perturbations
- Overdensities may form black holes strong field gravity is important
- Study in 3D (c.f. earlier work in spherical symmetry (Goldwirth & Piran, 1990))
- Use full numerical GR simulations to probe start of inflation beginning from initial conditions where gradient/kinetic energy dominates

イロト イポト イヨト イヨト 一日

- Einstein equations: $R_{ab} \frac{1}{2}Rg_{ab} = T_{ab}$
- Coupled to inflaton: $\Box \phi = V'(\phi)$
- Periodic boundary conditions: either numerical convenience or universe with torodial topology
- "Flat on average"

Initial conditions

$$\phi(t = 0, \mathbf{x}) = \phi_0 + \delta \phi \left[\sum_{1 \le |\mathbf{k}L/2\pi|^2 \le N} \cos(\mathbf{k} \cdot \mathbf{x} + \theta_{\mathbf{k}}) \right]$$

- Start with gradient dominated energy conditions $\langle \rho \rangle \approx \langle \rho_{\rm grad} \rangle$
- Inflationary energy scale is initially much smaller: $V_{Inflation} = 10^{-3} \langle \rho \rangle$
- Start with constant K (= -3H₀) set by average energy density
- Note that $H_0^2 \propto \rho(t = 0) \propto k^2 \delta \phi^2$ (Hamiltonian constraint)
- Hence different amplitudes corresponding to different values of H₀/k

イロト イポト イヨト イヨト 二日

Consider different values of k/H_0

- When k/H₀ >> 1 expect you should be able to average over inhomogeneities
- When k ~ H₀ expect black hole formation by hoop conjecture: mass in over density ~ size of over density (in geometric units)
- Hence becomes a strong-field gravity problem where gravitational collapse may spoil expansion
- When k/H₀ « 1 have superhorizon modes which act like curvature (not considering).

イロト イポト イヨト イヨト 三日

Inflaton values are entirely contained on the flat part of the potential — inflationary "plateau":

 $V \approx \Lambda$

Second case

Consider cases when average field value gives slow-roll inflation, but variations can exceed inflationary plateau.

Step and notch-like potentials (e.g. cosmological attractors from Kallosh & Linde, 2013)

Step function potential

Leaving the inflationary plateau

イロン イボン イヨン イヨン

ъ

When $\delta \phi > \phi_0$, field "feels" bottom of potential which rapidly pulls it to lower energy/non-inflationary values. For step-like potential:

- Average "force" on scalar field is proportional to $\langle V' \rangle = V/\langle \phi \rangle$
- Slow roll condition $M_{p}V'/V = \epsilon < 1$
- $\langle V'(\phi) \rangle \sim V(\langle \phi \rangle) / \langle \phi \rangle = (\frac{M_p}{\langle \phi \rangle})(\frac{V'(\langle \phi \rangle)}{\epsilon}) > V'(\langle \phi \rangle)$ for $\langle \phi \rangle < M_p / \epsilon$
- Similar nonlinear effects cause potential energy decrease for notch-like potential

◆□ → ◆□ → ◆三 → ◆三 → ● ● ● ● ●

Conclusion

- Inflation can proceed from a large class of initial inhomogeneous initial conditions — no need to initially assume Hubble-sized homogeneous patches
- Collapsing regions with black holes form, but exponentially expanding regions eventually dominate the volume
- Holds except when distance to end of inflationary plateau $\lesssim \delta \phi$

Future work:

- Consider wider class of initial conditions/potentials
- Fate of crunching regions potentially produced during inflation by metastability of the Higgs

Many interesting applications of tools from numerical GR to addressing inhomogeneous/strong-field cosmology questions (see e.g. Eloisa Bentivegna's talk from Monday).
