Holographic conductivity,
• The process of thermalization in QFT is poorly understood even today.

• It has been brought forward recently with the heavy ion collisions at RHIC and CERN.

• The data indicate rapid thermalization of the initial energy density and the formation of a quark gluon plasma.

• The thermalization time is an order of magnitude smaller than what was expected at RHIC and seems even smaller at LHC.

• The theory (QCD) is in a strongly coupled regime for most of the energy range of the experiments.

• The challenge is to understand thermalization in this context and more generally.

Holographic conductivity, Elias Kiritsis
The setup for thermalization

- We consider the theory in its vacuum state and then perturb it by a time dependent coupling constant (this is a simplification)

\[ L_{QFT} + f_0(t) \int d^4x \ O(x) \rightarrow \nabla^t \langle T_{tt} \rangle = \dot{f}_0 \langle O \rangle \]

- The approach to equilibration is controlled by the expectation values \( \langle T_{tt}(t) \rangle, \langle O \rangle(t) \).

- We expect that if the system thermalizes then

\[ \langle O \rangle(t \rightarrow \infty) \rightarrow Tr[\rho_{\text{thermal}} \ O] \]
To calculate the observables at strong coupling we will assume the holographic (AdS/CFT) correspondence (aka gauge/gravity duality).

Thermalization corresponds to black hole formation in the bulk spacetime.

_Holographic conductivity_, Elias Kiritsis
There are three possible characteristic times involved.

Holographic conductivity,
• There have been studies of this setup in CFTs (AdS space). There is no consensus yet but in most cases there is thermalization.  
  \[ \text{Chessler+Yaffe, Heller+Janik+Witaszczyk, Bizon+Rostorowski, Buchel+Liebling+Lehner} \]

• There are similarities between a conformal (scale-invariant) gauge theory and a **confining gauge theory (like QCD)** that has a non-trivial scale, $\Lambda_{QCD}$ but there are also **important differences**.

• Confinement is tracked by the Wilson loop that has area behavior in the confining phase.

\textit{Holographic conductivity,}  
\textbf{Elias Kiritsis}
The Hard Wall Model

There is a very simple holographic model for a confining gauge theory: The hard wall model.

The hard wall induces an IR scale and confinement.

---

Polchinski+Strassler
• In this simple model we can obtain analytic solutions for sufficiently small perturbations.

• Numerical solutions confirm these expectations.

• But the hard-wall model is too simple for many purposes.
• Holographic models were developed that describe with rather good accuracy the strong coupling physics of YM theory.

  \( \text{Gursoy+Kiritsis+Nitti, Gubser+Nellore} \)

• They contain the fields dual to the most important YM operators

\[
\phi \quad \Leftrightarrow \quad \text{Tr}[F^2] \\
g_{\mu\nu} \quad \Leftrightarrow \quad T_{\mu\nu}
\]

• The gravitational action is the Einstein Dilaton action with a potential.

\[
S_{IHQCD} = M^3 \int d^5x \sqrt{g} \left[ R - \frac{4}{3} (\partial\phi)^2 - V(\phi) \right]
\]

• The potential is in one-to-one correspondence with the YM \( \beta \)-function.

• At large values of \( \phi \), \( V \sim \sqrt{\phi} e^{\frac{4}{3} \phi} \).
Figure 4: (Color online) Same as in fig. 1, but for the $s/T^3$ ratio, normalized to the SB limit.
Figure 2: (Color online) Same as in fig. 1, but for the $\Delta/T^4$ ratio, normalized to the SB limit of $p/T^4$.
Therefore the picture of the thermalization process is as follows:

\[ V_{\text{IR}} \sim e^{\frac{4}{3} \sqrt{\varphi}} \]

\[ V_{\text{UV}} \sim \frac{12}{L^2} - \frac{4}{3 L^2} \Delta (\Delta - 4) \varphi^2 + \ldots \]

The Confining E-D

We will take for computational simplicity the operator dual to \( \phi \) to have UV dimension 3. This is not expected to affect qualitatively the results.
• Black holes can be characterized by their Hawking Temperature (two to one map), or the value of the scalar (dilaton) at the horizon $\lambda_H = e^{\phi_H}$ (one to one map).

• There are two black hole branches

(a) The large black hole branch.

(b) The small black hole branch. They are thermodynamically unstable with negative specific heat. As the horizon size vanishes the small black hole turns into the vacuum state solution.

• There is a minimum temperature $T > T_0$, that separates the large from the small black hole branch.

• The first order (deconfining) phase transition to the deconfined (black hole phase) happens at $T_c > T_0$ inside the large black hole branch.
Plots of the temperature scaled by the critical temperature as a function of $\frac{\lambda_H}{\lambda_c}$ (left) and the entropy density scaled by the third power of the temperature as a function of $\frac{T}{T_c}$ (right). The rightmost plot becomes “dotted” as one passes through the phase transition by lowering the temperature from above. This is meant to indicate that in the field theory, this low temperature phase is governed by the thermal gas solutions, whose entropy is subleading in the number of colors $N_c$.

Holographic conductivity,
Quench dynamics

- The quench profile is:

\[ f_0(v) = \tilde{f}_0 - \delta f_0 e^{-\frac{v^2}{2\tau^2}} \]

- For numerical simplicity we start with the theory in a thermal state that corresponds to the small black hole branch.

- The “smallest” the initial black hole, the closest we are to the initial (confining) ground state of the theory.
We find the following

- The characteristic time associated with the intermediate non-linear regime is negligible compared to $\tau$ and $T_{RD}$.

- This seems to be a generic occurrence in holography/gravity and a clean explanation is still lacking.

- Therefore

  $$T_{thermalization} \sim \frac{1}{\Gamma}$$

- For adiabatic perturbations, $\tau \gg 1$ the system does NOT oscillate but goes continuously to the final-state black hole.
Holographic conductivity,

Elias Kiritsis
The ring-down phase

\[ \delta \langle \hat{T}_{xx} \rangle \]

\[ \langle \hat{T}_{xx}(\nu) \rangle - \langle \hat{T}_{xx}(\infty) \rangle \]

\[ \alpha e^{-0.5\nu} \]

\[ \frac{1}{T_{\text{therm}}} \sim 2 \]
The temperature dependence of the decay width $\Gamma$ for the lowest lying scalar quasi-normal mode in several states of our theory. The blue circles are large black branes whose temperature is an integer multiple of $T_c$. The orange squares correspond to the minimum temperature black brane (top) and the smallest black hole we perturb in our study (bottom). The ratio $\Gamma/\pi T$ approaches 1.75953 (the dashed line) at high temperatures, which coincides with the expected value for perturbations of AdS$_5$ Schwarzschild by a dimension 3 scalar operator.

Holographic conductivity, Elias Kiritsis
The numerical data

\begin{align*}
\langle \hat{T}_{tt} \rangle & = 20 \\
\langle \hat{T}_{tt} \rangle & = 10 \\
\langle \hat{T}_{tt} \rangle & = 0 \\
\end{align*}

\begin{align*}
\frac{1}{\tau} & = 6 \\
\frac{1}{\tau} & = 5 \\
\frac{1}{\tau} & = 4 \\
\end{align*}

\begin{align*}
\delta f_0 & = 1 \\
\delta f_0 & = 0.5 \\
\delta f_0 & = 0.05 \\
\end{align*}

Conclusions and Outlook

- **Rapid Transitions to the linear regime**: The confinement scale plays little role for perturbations with $\frac{\langle T_{tt} \rangle}{\Lambda^4} \gtrsim 1$.

- **Universality and scaling in the abrupt quench limit**: Fast processes are only sensitive to (static) UV behavior.

- Other non-perturbative scaling regimes found, and need to be understood.

- The results are compatible (by extension) with an almost instant thermalization in QCD processes.

- The extension to the initial state being the ground state should be analyzed. A Choptuik-like phase transition is expected, but a different Choptuik exponent is expected.

The energy density $\langle \hat{T}_{tt} \rangle$ as a function of entropy $s$, in units of $f_0$ and with $\kappa = 1$. The asymptotic behaviors are $\langle \hat{T}_{tt} \rangle \propto s^{4/3}$ and $\langle \hat{T}_{tt} \rangle \propto s^{\sqrt{-\ln s}}$ in the limits of very large and very small black holes, and a fit for the former is plotted with a red dotted line. The green and magenta dots mark the locations of the first order phase transition at $T = T_c$ and the division between small and large black holes at $T = T_0$, respectively.

Holographic conductivity,

Elias Kiritsis
The area density of small black holes compared with that at the phase transition, $A_{Hc}$. The red dot marks the location in our space of solutions of the smallest black hole we perturb in this study. The dashed line indicates the location of the small and large black hole transition at $T = T_0$. As these are static black brane solutions, the apparent and event horizons coincide.
The blue and purple lines correspond to $\tilde{\delta} = 0.5$ and 1, respectively.
The blue and purple lines correspond to $\tilde{\delta} = 0.5$ and 1, respectively. In the case of the larger amplitude quench, it is interesting to note that the energy density appears to be driven below the ground state energy density (i.e. negative) in the first moments of the quench.
The blue and purple lines correspond to $\tilde{\delta} = 0.5$ and 1, respectively.
Example of the time evolution of the apparent (red) and event (blue) horizons. The event horizon coincides with the apparent horizon when the bulk solution is static, at $v \rightarrow \pm \infty$.
