Abstract. MicroBooNE is a liquid argon time projection chamber (LArTPC) neutrino experiment that is currently running in the Booster Neutrino Beam at Fermilab. LArTPC technology allows for high-resolution, three-dimensional representations of neutrino interactions. A wide variety of software tools for automated reconstruction and selection of particle tracks in LArTPCs are actively being developed. Short, isolated proton tracks, the signal for low-momentum-transfer neutral current (NC) elastic events, are easily hidden in a large cosmic background. Detecting these low-energy tracks will allow us to probe interesting regions of the proton's spin structure. An effective method for selecting NC elastic events is to combine a highly efficient track reconstruction algorithm to find all candidate tracks with highly accurate particle identification using a machine learning algorithm. We present our work on particle track classification using gradient tree boosting software (XGBoost) and the performance on simulated neutrino data.

1. Introduction

The three up and down valence quarks in the nucleon only account for a small percent of its mass. Gluons that bind the valence quarks split into quark-antiquark pairs of up, down, and strange flavor. This sea of quarks and gluons carries the remainder of the nucleon mass. The structure of the quark-gluon sea and how its elements combine with the valence quarks to give the nucleon its measured structure is not precisely known.

The net spin of the proton comes from a combination of the spin and orbital momentum of the quarks and gluons. The net contribution from the spin of strange quarks and antiquarks, Δs, is zero in the static quark model.

In the 1980s the European Muon Collaboration [1] and several subsequent experiments found that the Ellis-Jaffe Sum Rule was violated in polarized, charged-lepton, inclusive, deep inelastic scattering (DIS). The Ellis-Jaffe sum rule assumes that SU(3) flavor symmetry is valid and that $\Delta s = 0$. For the results to be consistent with exact SU(3) flavor symmetry, Δs must be *negative*. Follow-up measurements using semi-inclusive deep inelastic scattering have been consistent with $\Delta s = 0$, but these determinations of Δs are highly dependent on the fragmentation functions used [2].

An independent determination of Δs can be made using neutral-current (NC) elastic neutrino-proton scattering. The NC elastic cross section depends directly on Δs and no assumptions about SU(3) flavor symmetry or fragmentation functions are needed. Previous measurements

using elastic neutrino-proton scattering [3, 4, 5, 6] have been able to resolve final state protons down to a kinetic energy of $T \sim$ 240 MeV which corresponds to a momentum transfer of $Q^2 = 0.45$ GeV^2. These measurements also found $\Delta s < 0$, but the results are highly dependent on the choice of the axial form factor Q^2 dependence. To extract Δs, G_A^s must be extrapolated to $Q^2 = 0$. Detecting events with lower momentum transfer would lessen the dependence on the choice of the model. Global fits to electron-proton and neutrino-proton elastic scattering data have found $\Delta s = -0.30 \pm 0.42$. Based on data from a simulation of the MicroBooNE detector and the Booster Neutrino Beam (BNB), the uncertainty on the global fit to Δs is estimated to decrease by a factor of ten when including MicroBooNE data [7].

2. Elastic neutrino-proton scattering

The elastic lepton-nucleon scattering cross section depends on the axial, electric, and magnetic form factors which represent the finite structure of the nucleon. The axial form factor, G_A, represents the spin structure, and the electric and magnetic form factors, G_E and G_M, represent the electric and magnetic structure, respectively.

2.1. Neutral-current elastic scattering

The NC elastic neutrino-proton cross section [8] can be written in terms of the neutral-current form factors G_A^{NC}, G_E^{NC}, and G_M^{NC} that represent the finite structure of the proton. The electric and magnetic form factors of the proton have been determined in a world-wide measurement program of elastic electron-proton scattering using hydrogen targets and quasi-elastic electron-nucleon scattering using light nuclear targets (specifically deuterium and helium) [9, 10]. In the limit where the momentum transfer (Q^2) goes to zero, the quark contributions to the axial form factor, G_A^{NC}, become the net contribution of individual the quark spin to the proton spin so that

$$G_A^{NC}(Q^2 = 0) = \frac{1}{2}(-\Delta u + \Delta d + \Delta s).$$

The difference of the up and down spin contributions, $\Delta u - \Delta d$, is proportional to the axial vector coupling constant g_A measured in hyperon β decay [11], therefore a measurement of G_A^{NC} can determine Δs.

2.2. Experimental measurement

For free nucleon scattering, the final state of an NC elastic neutrino-proton interaction consists of a neutrino and a proton. Since it isn't possible to detect the outgoing neutrino, the signal is a single proton track. In order to extrapolate the axial form factor to zero, we need to detect very low energy protons. The kinematics of the interaction are determined entirely by the proton kinetic energy, T_P, by $Q^2 = 2T_P M_P$.

We estimate that MicroBooNE can detect NC elastic events down to a minimum of $Q^2 \sim 0.08$ GeV^2. The momentum transfer is determined by the kinetic energy of the proton in NC elastic interactions. MicroBooNE can detect protons with a track length of at least 1.5 cm which corresponds to a kinetic energy of $\sim$40 MeV in liquid argon giving $Q^2 \sim 0.08$ GeV^2. The set of events with a neutrino-proton final state is a subset of NC elastic scattering events, since the neutrinos are interacting with argon atoms and not free nucleons.

3. MicroBooNE

The MicroBooNE detector [12] is a liquid-argon time projection chamber (TPC) located in the Booster Neutrino Beam at Fermilab. MicroBooNE is a high-resolution detector designed to investigate the apparent excess of low-energy electron neutrino interactions seen in the MiniBooNE experiment [13]. MicroBooNE's ability to detect low-energy neutrino interactions
Figure 1. Proton track candidate in MicroBooNE data.

allows it to detect neutral current neutrino interactions with a low momentum transfer. It began taking data in October of 2015. Figure 1 shows an example of a proton track candidate in MicroBooNE.

The TPC [12] is 10 meters long in the beam direction, 2.3 meters tall, and 2.5 meters in the electron drift direction. It takes 2.3 ms for electrons to drift across the full width of the TPC in the electric field. Events are read out on three anode wire planes. In addition to the TPC, MicroBooNE has a light collection system with nanosecond timing resolution to collect scintillation light emitted by the liquid argon. The PMTs determine the initial time of the interaction to help with cosmic rejection. In order for an event to be read out, there must be an optical signal within a 23 μs window around the BNB spill.

3.1. Events in MicroBooNE
The data from each *event* in MicroBooNE can be visualized as a set of three high resolution images (one from each anode plane). Each image has approximately 20 million pixels (3,000 wires by 9,600 time ticks). It takes 30 MB of disk space to store one MicroBooNE event. In Fig. 1, the X-axis corresponds to wire number and the Y-axis corresponds to time tick. The dark blue background corresponds to no signal on the wire, and the colored pixels correspond to charge deposited on the wire. The color or intensity of the pixel corresponds to the amount of energy deposited in the TPC.

4. Automated event selection
MicroBooNE is close to the surface of the Earth, which results in a large cosmic ray background. This can be seen in the bottom image in Fig. 2. There are an average of twelve cosmic muon tracks per readout frame [14]. In addition, there are approximately five times as many event triggers caused by cosmic rays coincident with the BNB spill than actual neutrino interactions. During MicroBooNE's three year run, we expect to have ~200,000 neutrino interactions and ~1,000,000 cosmic interactions. This means that automated neutrino event reconstruction and identification algorithms are required. These algorithms are currently being developed for liquid argon TPCs.

4.1. Track reconstruction in LArSoft
Track reconstruction is handled in the Liquid Argon Software framework (LArSoft) [15]. One-dimensional hits are found by fitting Gaussian functions to noise-filtered [16] waveforms that are read out from the anode wires in the TPC. This is done for all of the wires on all three of the planes. The result is a two-dimensional image for each of the three wire planes, where the two dimensions are wire number and time. These 2D hits are used as inputs to the Pandora Software Development Kit [17]. Pandora contains pattern recognition algorithms that have been
Figure 2. 2D event display of a simulated neutral-current elastic event in MicroBooNE that was successfully classified as a proton. The left image shows the side view of the entire MicroBooNE TPC. The right image is a close-up event display of the simulated proton track. All of the additional tracks are from cosmic rays.

optimized to reconstruct tracks from neutrino interactions in liquid argon TPCs at the BNB energy range. The Pandora algorithms take a set of hits and reconstruct neutrino interaction vertices.

At this point the size of each event has been reduced from millions of pixels to about 20 reconstructed track objects with very little information loss. We can attempt to identify the type of particle and interaction that produced the set of tracks. In the NC elastic case, we want to specifically select proton tracks.

4.2. Proton track identification

Neutral-current elastic interactions are the most difficult to detect automatically because there is typically only one visible particle coming from the interaction vertex. There is no unique topology separating these events from the cosmic background.

Each reconstructed track object in a MicroBooNE event has several reconstructed physics properties associated with it. These properties fall into the categories of geometric, calorimetric, and optical. The geometric properties are related to the position, shape and size of the track. This includes variables like whether the track is entering the TPC, how long the track is, and how curvy a track is. Calorimetric properties all have to do with the charge deposited along the track. We can use information about how much total charge was deposited by the track, the average charge deposited per cm, and the difference between the amount of charge deposited at the beginning or the end of the track. We can also create variables that represent the shape and scale of the dE/dx (or dQ/dx) curve at any point along the reconstructed track. Additionally, we can use optical information from the PMT system to help characterize tracks. In this work we use the distance between the reconstructed track and the closest optical flash that was in the beam time window.

To identify proton tracks, we use a gradient-boosted decision tree classifier. We chose to use decision trees because they are easily interpretable and the inputs can be a mix of numeric and categorical variables. A detailed description of gradient decision tree boosting can be found in the documentation for the XGBoost[18, 19] software library that was used.

4.2.1. The decision tree model   We created a multi-class gradient-boosted decision tree classifier, using the XGBoost software library, to separate five different track types: any proton track, muons or pions from BNB neutrino interactions, tracks from electromagnetic showers from
Figure 3. The efficiency versus the purity of simulated protons selected by the boosted decision tree classifier for a series of proton probability cuts between zero and one. The dashed horizontal and vertical lines at 0.8 are there to guide the eye and correspond to a proton probability cut of approximately 30%.

BNB interactions, and any non-proton track produced by a cosmic ray interaction. The classifier takes reconstructed track features as input and outputs a probability of the track having been produced by each of the given particle types. The reconstructed features are based on the track's geometric, calorimetric, and optical properties.

The training data that we use to make the decision trees comes from Monte Carlo simulation. The BNB interactions are simulated using the GENIE neutrino generator [20, 21], and cosmic interactions are simulated using the CORSIKA cosmic ray generator [22]. The particles generated by GENIE and CORSIKA are passed to Geant4 [23, 24] where they are propagated through a simulated MicroBooNE detector. For training and testing of the trees we only use tracks that were reconstructed in LArSoft.

Of the reconstructed test tracks that were input to the classifier, 84% of the protons from simulated neutrino interactions, and 63% of the protons from simulated cosmic interactions were classified correctly as protons. Figure 3 shows the efficiency versus purity for different proton probability cuts in the range from zero to one. Figure 4 shows the protons from simulated neutrino interactions as a function of proton kinetic energy. Of the reconstructed test tracks that were classified as protons, 89% were true simulated protons (22% neutrino induced protons and 67% cosmic induced protons). Figure 5 shows the breakdown of track types that are classified as protons.

5. Conclusions

Whether the strange quarks in the nucleon sea contribute negatively or not at all to the spin of the nucleon is an open question. Neutrino NC elastic scattering offers a unique way to determine Δs that is independent of the assumptions required by previous measurements. The MicroBooNE liquid argon TPC can detect low-Q^2 NC elastic events and is currently taking neutrino data at Fermilab. Automated event reconstruction and selection methods are being developed to analyze the large amount of high-resolution neutrino events in MicroBooNE. In these proceeding, we summarize the current status of MicroBooNEs automatic reconstruction and identification of proton tracks in neutral-current and charged-current interactions. The automated reconstruction chain in MicroBooNE successfully reduces the size of the events from millions of pixels to individual reconstructed track objects. This allows us to use boosted decision trees for proton identification. The boosted decision tree model presented here correctly classifies 84% of simulated protons from neutrino interactions, and can be improved with further tuning to the decision tree model and the simulation.
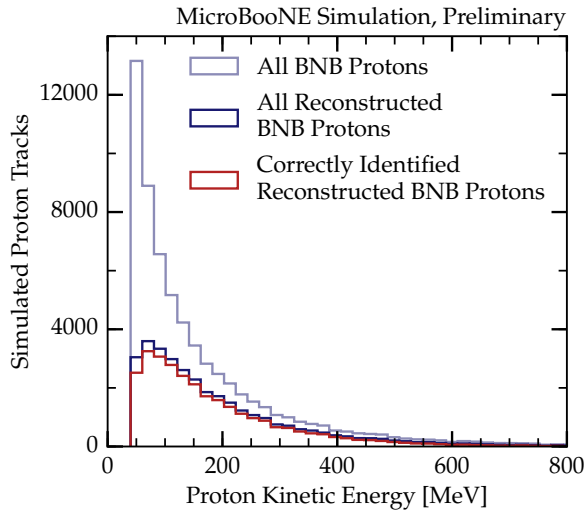

Figure 4. Simulated proton tracks as a function of kinetic energy. The light blue shows the full set of protons from simulated BNB neutrino interactions. The dark blue shows the number of those tracks that were reconstructed with the Pandora algorithms. The red line shows the subset of the reconstructed tracks that are classified as protons by the boosted decision trees.
Figure 5. Simulated particle types that are classified as protons by the boosted decision trees as a function of reconstructed length. Light blue shows simulated cosmic-induced protons, and dark blue shows the protons from simulated BNB neutrino interactions. The tan area shows all other simulated cosmic tracks, and the red area shows all other tracks from simulated BNB neutrino interactions.
