Antihydrogen offers a unique way to test matter/antimatter symmetry. Antihydrogen can reproducibly be synthesised and trapped in the laboratory for extended periods of time [1][2], offering an opportunity to study the properties of antimatter with high precision. The ALPHA collaboration at CERN has developed an experiment capable of accumulating several tens of trapped antihydrogen atoms [3], and interrogating the bound state energy structure using resonant microwaves [4] and laser light [5]. These recent results demonstrate that spectroscopic measurements of trapped antihydrogen are possible, and the collaboration is firmly en-route towards high precision measurements. Here, I present an overview of the ALPHA apparatus and the techniques which have been developed for measuring the spectrum of antihydrogen.
