- Conclusion

Prehistory: colliding $\gamma^*\gamma^*$ photons

(γ^* -virtual, quasi-real photon)

The idea to study some physics in photon-photon collisions is about 75 years old. The problem: a source of high energy photons.

In 30-th, Fermi-Weizsacker-Williams noticed that the field of a charged particle can be treated as the flux of almost real photons.

Such two-photon processes have been discovered and studied at all e^+e^- storage rings since 1970th

$X = e^+e^-, \mu^+\mu^-, \dots \eta'(960) \dots$, any C^+ resonances

$$m_\gamma \geq m_e / \gamma$$

Landau-Lifshitz processes

Physics in $\gamma^*\gamma^*$ is quite interesting, though it is difficult to compete with e^+e^- collisions because the number of equivalent photons is rather small and their spectrum soft

$$dn_\gamma \approx \frac{2\alpha}{\pi} \frac{dy}{y} \left(1 - y + \frac{1}{2} y^2\right) \ln \frac{E}{m_e} \sim 0.035 \frac{d\omega}{\omega};$$

$$L_{\gamma\gamma}(z > 0.1) \sim 10^{-2} L_{e^+e^-}$$

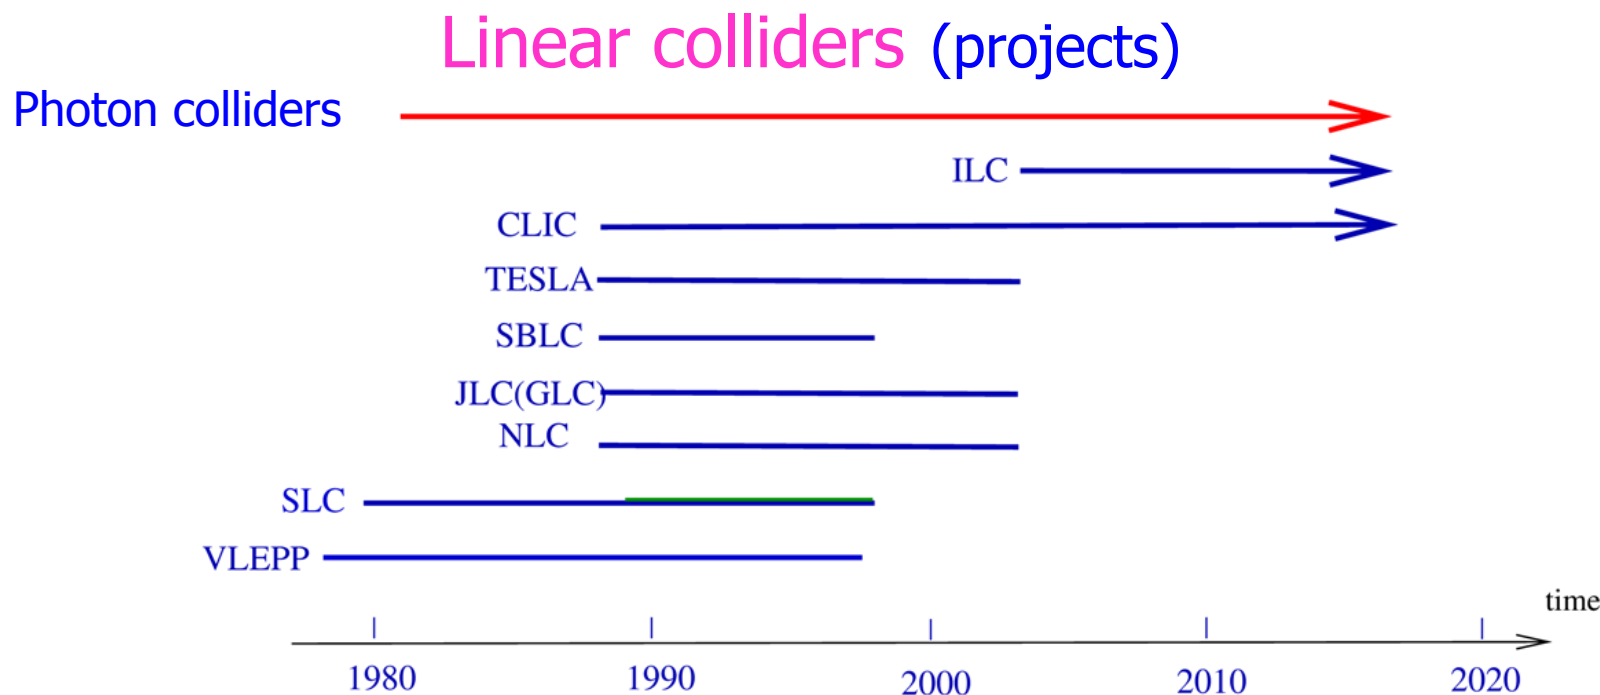

$$L_{\gamma\gamma}(z > 0.5) \sim 0.4 \cdot 10^{-3} L_{e^+e^-}$$

$$z = W_{\gamma\gamma} / 2E_0$$

Idea of the photon collider (1981) based on one pass linear colliders

The idea of the high energy photon collider was proposed at the first workshop on physics at linear collider VLEPP (Novosibirsk, Dec. 1980) and is based on the fact that at linear e^+e^- (e^-e^-) colliders electron beams are used only once which makes possible to convert electron beam to high energy photons just before the interaction point.

The best way of $e \rightarrow \gamma$ conversion is the Compton scattering of the laser light off the high energy electrons (laser target). Thus one can get the energy and luminosity in $\gamma\gamma$, γe collisions close to those in e^+e^- collisions: $E_\gamma \sim E_e$; $L_{\gamma\gamma} \sim L_{e-e^-}$

Scheme of $\gamma\gamma$, γe collider

$$\omega_m = \frac{x}{x+1} E_0$$

$$x \approx \frac{4E_0\omega_0}{m^2c^4} \approx 15.3 \left[\frac{E_0}{\text{TeV}} \right] \left[\frac{\omega_0}{\text{eV}} \right]$$

$$E_0 = 250 \text{ GeV}, \omega_0 = 1.17 \text{ eV}$$

$$(\lambda = 1.06 \text{ } \mu\text{m}) \Rightarrow$$

$$x=4.5, \omega_m=0.82E_0=205 \text{ GeV}$$

$x = 4.8$ is the threshold for $\gamma\gamma_L \rightarrow e^+e^-$ at conv. reg.

$$\omega_{\text{max}} \sim 0.8 E_0$$

$$W_{\gamma\gamma, \text{max}} \sim 0.8 \cdot 2E_0$$

$$W_{\gamma e, \text{max}} \sim 0.9 \cdot 2E_0$$

Electron to Photon Conversion

Spectrum of the Compton scattered photons

λ_e – electron longitudinal polarization
 P_c – helicity of laser photons, $x \approx \frac{4E_0\omega_0}{m^2c^4}$

Mean helicity of the scattered photons ($x = 4.8$)

(in the case **a**) photons in the high energy peak have $\lambda_\gamma \approx 1$)

The cross section of the Higgs production

$$\sigma(\gamma\gamma \rightarrow h) \propto 1 + \lambda_1\lambda_2$$

The cross section for main background

$$\sigma(\gamma\gamma \rightarrow b\bar{b}) \propto 1 - \lambda_1\lambda_2$$

Linear polarization of photons

$$\sigma \propto 1 \pm l_{\gamma 1} l_{\gamma 2} \cos 2\varphi \quad \pm \text{ for CP}=\pm 1$$

Linear polarization helps to separate H and A Higgs bosons

The optimum laser wavelength

The maximum energy of photons after the Compton scattering

$$\omega_{\max} \approx \frac{x}{x+1} E_0, \quad x = \frac{4E_0\omega_0}{m^2 c^4}$$

For $x > 4.8$ the luminosity in the high energy lum. peak decreases due to e^+e^- pair creation in collision of laser and high energy photons at the conversion point.

For the maximum collider energy E_0 the optimum laser wave length ($x=4.8$) is

$$\lambda [\mu\text{m}] \approx 4E_0[\text{TeV}]$$

$\lambda = 1 \mu\text{m}$ for $2E_0 < 500\text{--}600 \text{ GeV}$,
 $\lambda = 2 \mu\text{m}$ for $2E_0 < 1.2 \text{ TeV}$

Laser flash energy

For $e \rightarrow \gamma$ conversion one needs thickness (t) of laser target equal about one Compton collision length ($p=t/\lambda_c \sim 1$). The required flash energy is determined by σ_c , geometric properties of laser and electron beams and by nonlinear effects in Compton scattering described by parameter $\xi^2 = \frac{e^2 \bar{F}^2 \hbar^2}{m^2 c^2 \omega_0^2} = \frac{2n_\gamma r_e^2 \lambda}{\alpha}$ which should be kept small (0.15-0.3),

because
$$\omega_m = \frac{x}{x+1+\xi^2} E_0 .$$

It is reasonable to keep

$$\Delta\omega_m / \omega_m \approx \xi^2 / (x+1) < 0.05$$

then for $x=4.8$ $\xi^2 < 0.3$

For $\lambda=1 \mu\text{m}$ ($2E_0=500 \text{ GeV}$) the required flash energy is about $A \sim 10 \text{ J}$ and it increases for larger λ (or E_0) due to the nonlinear effect. It is determined by laser diffraction and geometric beam parameters at short λ and by nonlinear effects at large λ (multiTeV collider).

Typical $\gamma\gamma$, γe luminosity spectra

simulation with account all important effect at CP and IP regions:
multiple Compton scattering in CP, beamstrahlung, coherent pair creation,
beam repulsion e.t.c.

ILC(500)

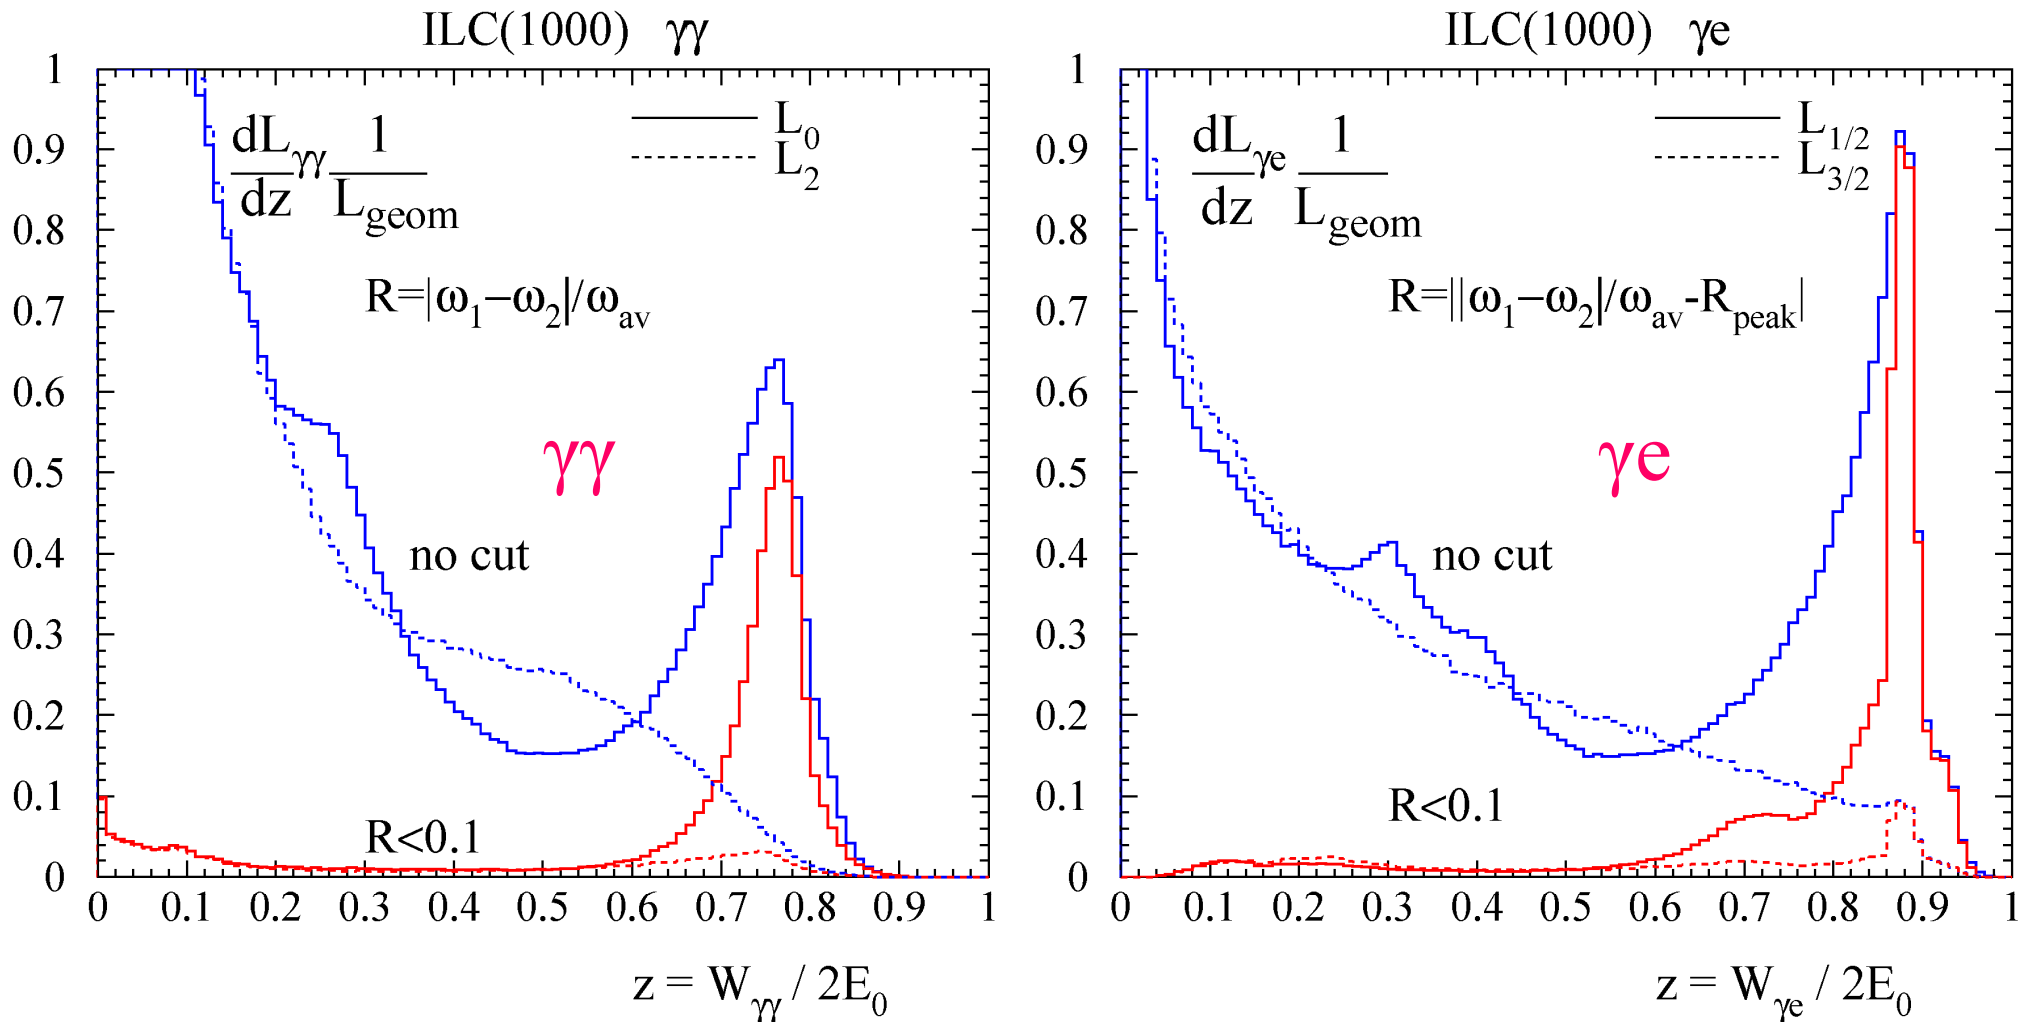

Luminosity spectra
and their polarization
properties can be
measured using QED
processes

$$L_{\gamma\gamma}(z > 0.8z_m) \sim 0.1 L_{e-e}(\text{geom})$$

Luminosity spectra at ILC(1000) with $\lambda=2 \mu\text{m}$

(red curves with restriction on longitudinal momentum of produced system)

Such $\gamma\gamma$ collider would be the best option for study of X(750)

(fake $\gamma\gamma$ peak observed at LHC in 2015-2016)

Removal of disrupted beams, crossing angle, beamdump

Removal of disrupted beams from the detector is one of most serious problem for the photon collider. After the interactions beams have very wide energy spread: $E \approx (0.02-1)E_0$ and large disruption angle (about 10 mrad at ILC). The problem is solved by using crab-crossing scheme where beams travels outside final quads.

$$\theta_d \propto \sqrt{N / \sigma_z E_{\min}} \propto \sqrt{\frac{N}{\sigma_z \sigma_c(x) \lambda}}$$

Angular size of quads $5/400 \sim 12$ mrad, so for PLC at ILC crossing angle about 25 mrad is needed (14 mrad is now for $e+e^-$). Using $\lambda = 2 \mu\text{m}$ (instead of $1 \mu\text{m}$) allows to decrease α_c from 25 to 20 mrad, this solution completely compatible with $e+e^-$.

Disrupted beam with account of the detector field (at the front of the first quad at L=4 m)

$2E_0=500$ GeV, $\lambda=1$ μm
 $E_{\text{min}} \approx 5$ GeV
 $\alpha_c=25$ mrad

$2E_0=1000$ GeV, $\lambda=2$ μm

→ $\alpha_c=20$ mrad will be OK
 same for CLIC (N/σ_z is quite similar)

The dependence of $W_{\gamma\gamma}$ on the laser wavelength

Here $W_{\gamma\gamma}$ corresponds to the peak of lum. spectra

The energy $2E_0$ required for the study of the H(125) and top threshold

λ , μm	1	1.5	2	
H (125)	210	235	255	21%
top(360)	485	520	550	13.4%

In order to have at the PLC with $\lambda=2 \mu\text{m}$ the same energy reach as with $\lambda=1 \mu\text{m}$ with $2E_0=500 \text{ GeV}$ one need $2E_0=565 \text{ GeV}$ (or 13% higher only).¹⁵

ILC TDR Layout

e- Main Linac

e+ Main Linac

E+ source

L=31 km
2E=500 GeV

Parameters	Value
C.M. Energy	500 GeV
Peak luminosity	$1.8 \times 10^{34} \text{ cm}^{-2}\text{s}^{-1}$
Beam Rep. rate	5 Hz
Pulse duration	0.73 ms
Average current	5.8 mA (in pulse)
E gradient in SCRF acc. cavity	31.5 MV/m +/-20% $Q_0 = 1\text{E}10$

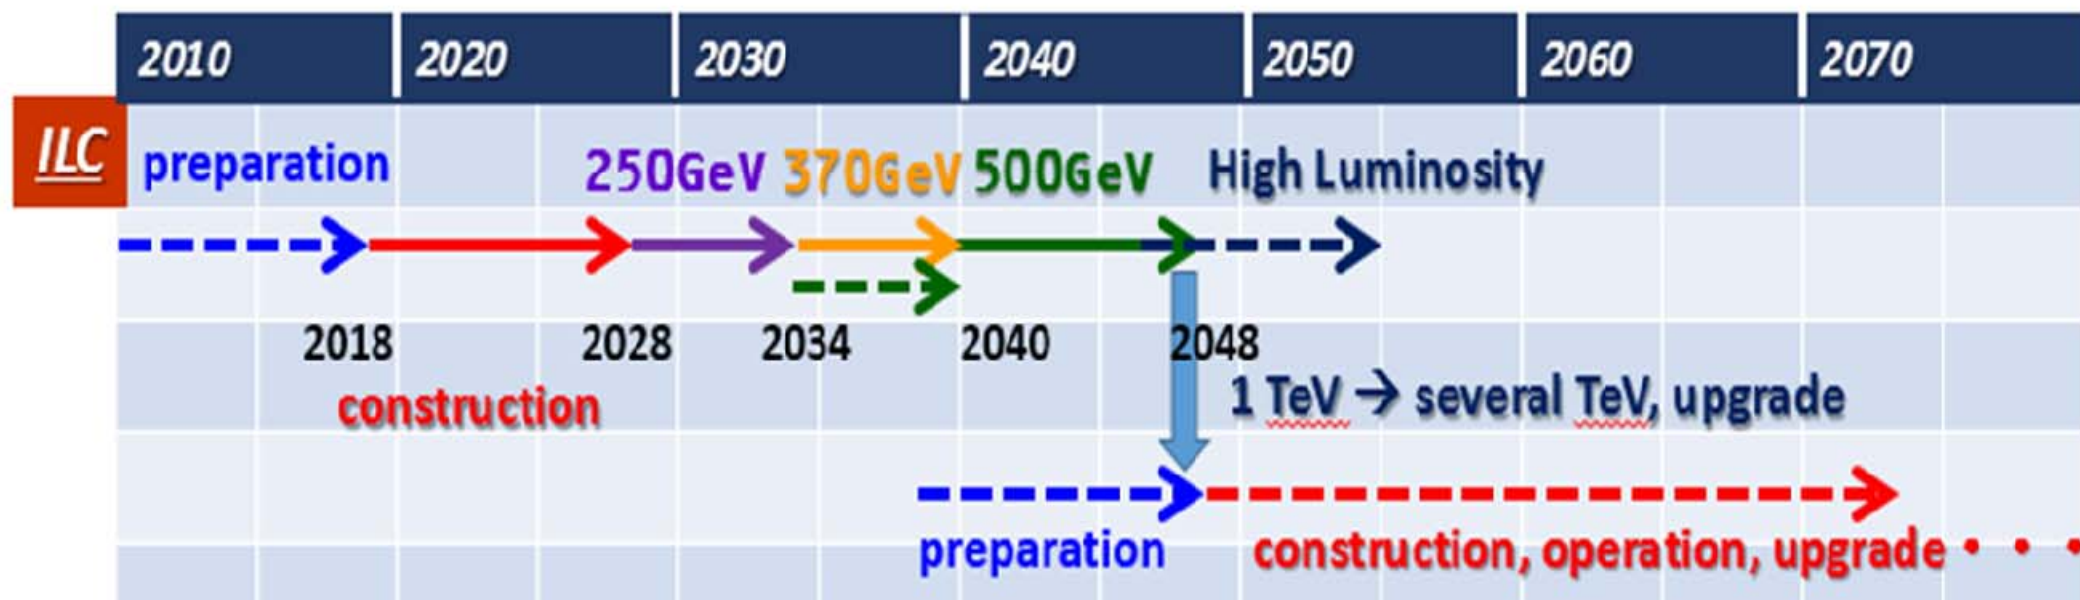

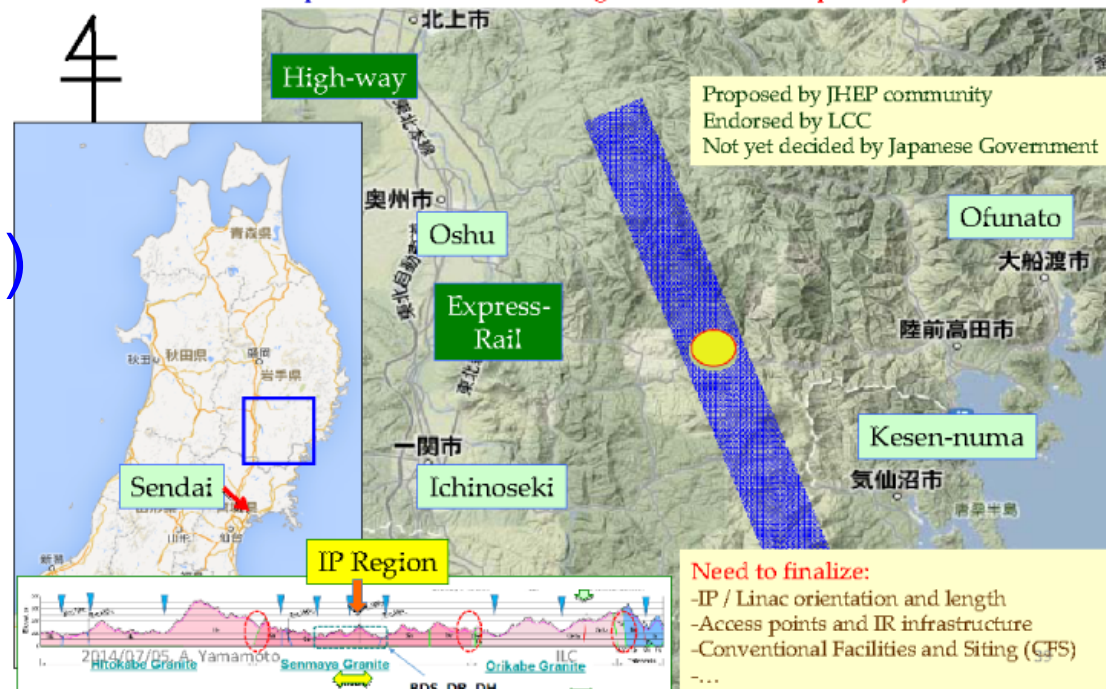

2E=250-500 GeV, upgradable to 1000 GeV

Japan is interested to host

- decision ~2018
- construction ~2019 (~10 years)
- physics ~2030

ILC Site Candidate Location in Japan: Kitakami Area

Establish a site-specific Civil Engineering Design - map the (site independent) TDR baseline onto the preferred site - assuming "Kitakami" as a primary candidate

ILC, last news from LCWS 2017 (Oct.)

At present Japan consider ILC with $2E=250$ GeV, without any words about possible upgrade (but possible). Thus the cost was reduced by 40% compared to 500 GeV.

Staging

ILC 500GeV

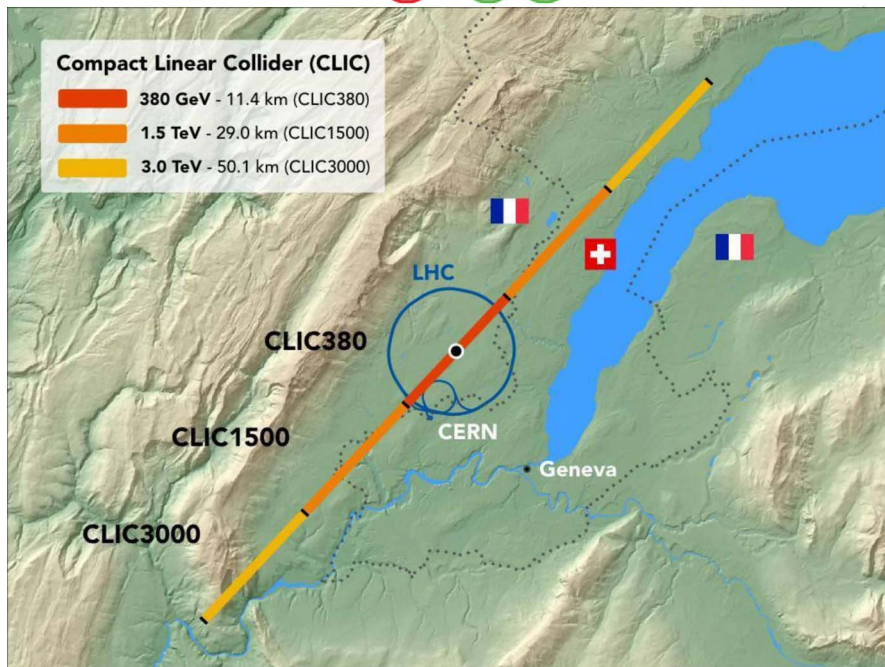

ILC 250GeV

This energy is OK for $e^+e^- \rightarrow ZH$ (no $t\bar{t}$) and for $\gamma\gamma \rightarrow H$ as well

CLIC

CLIC layout (3 TeV)

New CLIC layout 380 GeV

16

Present plans:

the initial energy $2E=380$ GeV (H and top)

2019-20 – decision

2020-2025 – preparation phase

2025 – construction starts

2035 – first beams

Requirements for the ILC laser system

- Wavelength $\sim 1 \mu\text{m}$ (good for $2E < 0.8 \text{ TeV}$)
- Time structure $\Delta t \sim 100 \text{ m}$, 3000 bunch/train, 5 Hz
- Flash energy $\sim 5\text{-}10 \text{ J}$
- Pulse duration $\sim 1\text{-}2 \text{ ps}$

If a laser pulse is used only once, the average required power is $P \sim 150 \text{ kW}$ and the power inside one train is 30 MW! Fortunately, only 10^{-9} part of the laser photons is knocked out in one collision with the electron beam, therefore the laser bunch can be used many times.

The best is the scheme with accumulation of very powerful laser bunch is an **external optical cavity**. The pulse structure at ILC (3000 bunches in the train with inter-pulse distance $\sim 100 \text{ m}$) is very good for such cavity. **It allows to decrease the laser power by a factor of 100-300.**

Laser system

Ring cavity (schematic view)

Telnov, 2000

The cavity includes adaptive mirrors and diagnostics. Optimum angular divergence of the laser beam is $\pm 30 \text{ mrad}$, $A \approx 9 \text{ J}$ ($k=1$), $\sigma_t \approx 1.3 \text{ ps}$, $\sigma_{x,L} \sim 7 \text{ } \mu\text{m}$

Recently new option has appeared, one pass laser system,
based on new laser ignition thermonuclear facility

Project LIFE, LLNL 16 Hz, 8.125 kJ/pulse, 130 kW aver. power
(the pulse can be split into the ILC train)

Laser diodes cost go down at mass production, that makes one pass laser system for PLC at ILC and CLIC realistic!

This project is not approved yet

Laser system for CLIC

Requirements to a laser system for PLC at CLIC (500)

Laser wavelength	$\sim 1 \mu\text{m}$ (5 for $2E=3000 \text{ GeV}$)
Flash energy	$A \sim 5 \text{ J}$, $\tau \sim 1 \text{ ps}$
Number of bunches in one train	354
Length of the train	$177 \text{ ns} = 53 \text{ m}$
Distance between bunches	0.5 ns
Repetition rate	50 Hz

The train is too short for the optical cavity, so one pass laser should be used.
The average power of one laser is 90 kW (two lasers 180 kW).

One pass laser system, developed for LIFE (LLNL) is well suited for CLIC photon collider at $2E=500 \text{ GeV}$.

MultiTeV CLIC needs lasers with longer wavelength: $\lambda \approx 4E_0[\text{TeV}], \mu\text{m}$

The discovery of the Higgs boson in 2012 has triggered several proposal of photon collider Higgs factories (without e^+e^-):

Photon collider Higgs factories

$\gamma\gamma$ Higgs factories appeared in 2012-2013 years

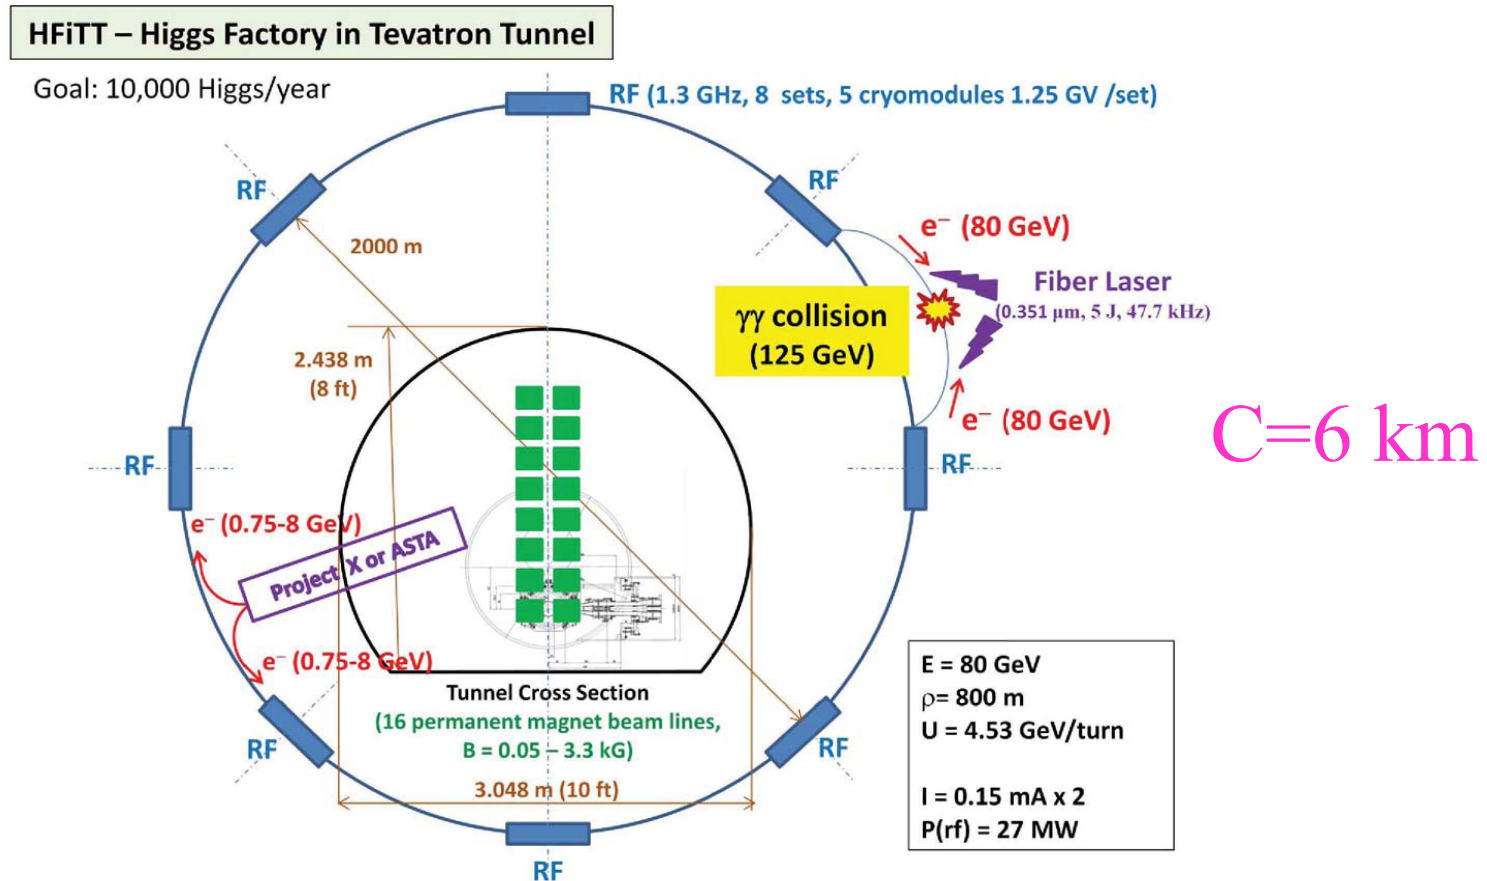

Figure 3: *Sketch of a layout for a $\gamma\gamma$ collider based on recirculating superconducting linacs – the SAPPHiRE concept.*

The scheme is based on LHeC electron ring, but shorter bunches and somewhat higher energy, 80 GeV

HFiTT – Higgs Factory in Tevatron Tunnel

W. Chou, G. Mourou, N. Solyak, T. Tajima, M. Velasco

The total number of beamlines in the tunnel will be 16, with the total length of approximately 96 km. The eight arcs would be stacked one on top another, so during the acceleration beams jump up and down, by about 1,5 m, 128 times! The vertical emittance will be certainly destroyed on such “mountains”.

Laser for HFiTT

Fiber Lasers -- Significant breakthrough

Gerard Mourou et al., "The future is fiber accelerators,"
Nature Photonics, vol 7, p.258 (April 2013).

ICAN – International Coherent Amplification Network

Figure 2: Principle of a coherent amplifier network (CAN) based on fiber laser technology. An initial pulse from a seed laser (1) is stretched (2), and split into many fibre channels (3). Each channel is amplified in several stages, with the final stages producing pulses of ~1 mJ at a high repetition rate (4). All the channels are combined coherently, compressed (5) and focused (6) to produce a pulse with an energy of >10 J at a repetition rate of 10 kHz (7). [3]

10 J, 10 kHz

Very good approach for equal spacing between bunches and problematic for collider with bunch trains, such as ILC, CLIC, because need very high diode peak power.

Plasma people also like photon colliders, because acceleration of electron is much easier than positrons

4 GeV beam in 9 cm plasma cell is produced (6% energy spread)

Physics motivation for the photon collider at LC

(shortly, independent on a physics scenario)

In $\gamma\gamma$, γe collisions compared to e^+e^-

- the energy is smaller only by 10-20%
- the number of interesting events is similar or even higher
- access to higher particle masses (H,A in $\gamma\gamma$, charged and light neutral SUSY in γe)
- higher precision for some phenomena ($\Gamma_{\gamma\gamma}$, CP-proper.)
 $\Gamma(H \rightarrow \gamma\gamma)$ width can be measured with statistics ≈ 60 times higher than in e^+e^- collisions.
- different types of reactions (different dependence on theoretical parameters)

It is the unique case when linear colliders allow to study new physics in several types of collisions at the cost of very small additional investments

Unfortunately, the physics in LC region is not so rich as expected, by now LHC found only light Higgs boson.

The resonance Higgs production is one of the gold-plated processes for PLC

Very sensitive to high mass particles in the loop

$$\dot{N}_H = L_{ee} \times \frac{dL_{0,\gamma\gamma}}{dW_{\gamma\gamma} L_{ee}} \frac{4\pi^2 \Gamma_{\gamma\gamma}}{M_H^2} (1 + \lambda_1 \lambda_2 + CP * l_1 l_2 \cos 2\varphi) = L_{ee} \sigma$$

$$\sigma = \frac{0.98 \cdot 10^{-35}}{2E_0[\text{GeV}]} \frac{dL_{0,\gamma\gamma}}{dz L_{ee}} (1 + \lambda_1 \lambda_2 + CP * l_1 l_2 \cos 2\varphi), \text{ cm}$$

For realistic ILC conditions $\sigma(\gamma\gamma \rightarrow H) \approx 75 \text{ fb}$, while $\sigma(e^+e^- \rightarrow HZ) \approx 290 \text{ fb}$

in e^+e^- $N(H \rightarrow \gamma\gamma) \propto L \sigma(e^+e^- \rightarrow HZ) \text{Br}(H \rightarrow \gamma\gamma)$, where $\text{Br}(H \rightarrow \gamma\gamma) = 0.0024$

in $\gamma\gamma$ $N(H \rightarrow \gamma\gamma) \propto L \sigma(\gamma\gamma \rightarrow H) \text{Br}(H \rightarrow b\bar{b})$, where $\text{Br}(H \rightarrow b\bar{b}) = 0.57$

Conclusion: in $\gamma\gamma$ collisions the $\Gamma(H \rightarrow \gamma\gamma)$ width can be measured with statistics $(75 \cdot 0.57) / (290 \cdot 0.0024) = 60$ times higher than in e^+e^- collisions.

That is one of most important argument for the photon collider.

Remark on Photon collider Higgs factories

Photon collider can measure

$\Gamma(H \rightarrow \gamma\gamma) \cdot \text{Br}(H \rightarrow bb, ZZ, WW)$, $\Gamma^2(H \rightarrow \gamma\gamma)/\Gamma_{\text{tot}}$, Higgs CP properties (using photon polarizations). In order to get $\Gamma(H \rightarrow \gamma\gamma)$ one needs $\text{Br}(H \rightarrow bb)$ from e^+e^- (accuracy about 1%). As result the accuracy of $\Gamma(H \rightarrow \gamma\gamma)$ is about 1.5-2% after 1 years of operation. Other Higgs decay channels will be unobservable due to large QED background.

e^+e^- can also (in addition) measure $\text{Br}(bb, cc, gg, \tau\tau, \mu\mu, \text{invisible})$, Γ_{tot} , less backgrounds due to tagging of Z.

Therefore PLC is nicely motivated in only in combination with e^+e^- : parallel work or second stage.

Some examples of Physics (in addition to H(125))

Charged pair production in e^+e^- and $\gamma\gamma$ collisions.

unpolarized beams $(S \text{ (scalars), } F \text{ (fermions), } W \text{ (W-bosons); } \sigma = (\pi\alpha^2/M^2)f(x), \text{ beams unpolarized})$

polarized beams

So, typical cross sections for charged pair production in $\gamma\gamma$ collisions is larger than in e^+e^- by one order of magnitude (circular polarizations helps)

Not seen at LHC

Supersymmetry in $\gamma\gamma$

In supersymmetric model there are 5 Higgs bosons:

h^0 light, with $m_h < 130$ GeV

H^0, A^0 heavy Higgs bosons;

H^+, H^- charged bosons.

$M_H \approx M_A$, in e^+e^- collisions H and A are produced in pairs (for certain param. region), while in $\gamma\gamma$ as the single resonances, therefore:

in e^+e^- collisions $M_{H,A}^{max} \sim E_0$ ($e^+e^- \rightarrow H + A$)

in $\gamma\gamma$ collisions $M_{H,A}^{max} \sim 1.6E_0$ ($\gamma\gamma \rightarrow H(A)$)

For some SUSY parameters H, A can be seen only in $\gamma\gamma$
(but not in e^+e^- and LHC)

Not seen at LHC

Supersymmetry in γe

At a γe collider charged particles with masses higher than in e^+e^- collisions at the same collider can be produced (a heavy charged particle plus a light neutral one, such as a new W' boson and neutrino or supersymmetric charged particle plus neutralino):

$$m_{\tilde{e}^-} < 0.9 \times 2E_0 - m_{\tilde{\chi}_1^0}$$

Not seen at LHC

$\gamma\gamma$ collider for c,b-quark energy region
 $W_{\gamma\gamma}=3-12 \text{ GeV}$

Linear colliders on 0.3-1.5 TeV energies are still not approved (due to high cost and uncertain physics case), beside the photon collider based at ILC (CLIC) can appear as the second stage in 3-4 decades, therefore it has sense to consider a $\gamma\gamma$ collider on the energy $W_{\gamma\gamma}=3-12$ GeV

c-b $\gamma\gamma$ -factory

It is a natural choice, because it is the region of b-quark bound states (and there is nothing interesting between 12 and 125 GeV).

This energy region was studied in e^+e^- collisions at B-factories (KEK and SLAC) and will be further studied with much high luminosity at new SuperB-factory. However these e^+e^- factories can not study $\gamma\gamma$ collisions at $W_{\gamma\gamma}=6-12$ GeV (too low $\gamma^*\gamma^*$ luminosity).

The LHC is not suited for detailed study of $\gamma\gamma$ physics because there is very large background due to strong interactions (such as pomeron-pomeron interactions) with very similar final states.

Two real photons will produce resonance states with $Q = 0$, $C = +$, $J^P = 0^+, 0^-, 2^+, 2^-, 3^+, 4^+, 4^-, 5^+ \dots (\text{even})^\pm, (\text{odd} \neq 1)^+$ as well as numerous 4-quark (or molecule) states similar to those observed in e^+e^- .

The required electron beam energy $E_0 \sim 17-23$ GeV (for $\lambda=0.5$ and $1 \mu\text{m}$), 10 time smaller than ILC, so the cost will be smaller accordingly.

Scheme of the collider

There are many possible electron “drivers”
for C-b- $\gamma\gamma$ -collider:

- 1) SC European 17.5 GeV XFEL (used beams?)
- 2) Warm cavity linac (CLIC structure with klystrons)
- 3) Plasma accelerator (dream)

New linac can be used simultaneously
for X-FELS.

European Superconducting XFEL has started operation in 2017. Its e-beam parameters:
 $E_0=17.5$ GeV, $N=0.62 \cdot 10^{10}$ (1 nQ), $\sigma_z=25$ μm , $\varepsilon_n=1.4$ mm mrad, $f \approx 30$ kHz

Using arcs with $R \sim 100$ -200 m we can get the photon collider with $f=15$ kHz.
 Other parameters for $\gamma\gamma$ collider: $\beta^*=70$ μm , $\sigma_z=70$ μm , laser wavelength $\lambda=0.5$ μm ,
 we get the following $\gamma\gamma$ luminosity spectra:

Unpolarized electrons, $P_c=-1$

Polarized electrons, $2\lambda_e P_c=-0.85$

$W_{\gamma\gamma}$ peak at 12 GeV, covers all bb-meson region. Electron polarization is desirable, but not mandatory (improvement < 1.5 times). Easy to go to lower energies by reducing the electron beam energy.

By increasing the CP-IP distance the luminosity spectrum can be made more narrow and cleaner

One example: $\gamma\gamma \rightarrow \eta_b$.

There was attempt to detect this process at LEP-2 ($2E=200$ GeV, $L=10^{32}$, but only upper limit was set.

$$N = \frac{dL_{\gamma\gamma}}{dW_{\gamma\gamma}} \frac{4\pi^2 \Gamma_{\gamma\gamma} (1 + \lambda_1 \lambda_2)}{M_x^2} \left(\frac{\hbar}{c} \right)^2 t$$

For $\gamma\gamma$ collider $\frac{dL_{\gamma\gamma} 2E_0}{dW_{\gamma\gamma} L_{ee}} \simeq 0.5$, so

$$N \sim \frac{\pi^2 \Gamma_{\gamma\gamma} (1 + \lambda_1 \lambda_2)}{E_0 M_x^2} \left(\frac{\hbar}{c} \right)^2 (L_{ee} t) \sim 8 \cdot 10^{-27} \frac{\Gamma_{\gamma\gamma}}{E_0 M_x^2 [\text{GeV}^2]} (L_{ee} t)$$

For $\Gamma_{\gamma\gamma}(\eta_b) = 0.5$ keV, $E_0 = 17.5$ GeV, $M(\eta_b) = 9.4$ GeV, $\lambda_{1,2} = 1$, $L_{ee} = 1.6 \cdot 10^{33} - 2.3 \cdot 10^{34}$,
 $t = 3 \cdot 10^7$ s we get $N(\eta_b) \approx 1.5 \cdot 10^5 - 2 \cdot 10^6$ and can measure its $\Gamma_{\gamma\gamma}$

Production rate is higher than was at LEP-2 (in central region) $\sim 700 - 10^4$ times!

Parameters of photon collider for bb-energy region ($W < 12$ GeV)

V. Telnov

E_0 , GeV	17.5 (23)
$N/10^{10}$	0.62
f , kHz	15
σ_z , μm	70
$\varepsilon_{nx}/\varepsilon_{ny}$, mm mrad	0.1/0.1
β_x/β_y , μm	70/70
σ_x/σ_y , nm	14/14
laser λ , μm	0.5 (1)
laser flash energy, J	3 ($\xi^2=0.05$)
$f\#$, τ , ps	27, 2
crossing angle, mrad	~ 30
b , (CP-IP dist.), mm	0.5
L_{ee} , 10^{34}	2.3
$L_{\gamma\gamma}(z > 0.5z_m)$, 10^{34}	0.3
$W_{\gamma\gamma}(\text{peak})$, GeV	12

In Table the low emittance plasma gun is assumed. With the XFEL gun the luminosity is smaller ~ 15 times.

In order to get $W_{\gamma\gamma} \leq 12 \text{ GeV}$ one needs

$E_0 = 17.5 \text{ GeV}$ and $\lambda = 0.5 \text{ } \mu\text{m}$

or $E_0 = 23 \text{ GeV}$ and $\lambda = 1 \text{ } \mu\text{m}$

Polarization

Gamma beams have high degree of circular or linearly polarization at maximum energies that allows to measure easily S and P-parity of resonances ($C=+$)

Absence of e^+e^- induced backgrounds

At e^+e^- colliders, after emission of ISR e^+e^- can produce $C=-$ resonances which looks similar to $\gamma\gamma$ resonances.

At e^-e^- based $\gamma\gamma$ -collider there are no such backgrounds

Requirements for the laser system

- Wavelength $\sim 0.5\text{-}1\ \mu\text{m}$ ($1\ \mu\text{m}$ needs 30% high electron energy)
- Flash energy $\sim 3\ \text{J}$
- Pulse duration $\sim 2\ \text{ps}$
- Time structure same as electron linac
 - a) for SC XFEL linac $\Delta t \sim 100\ \text{m}$, 3000 bunch/train, 5 Hz
 - b) for CLIC linac $\Delta t \sim 15\ \text{cm}$, 350 bunch/train, 50 Hz
 - c) plasma linac equidistantly 30 kHz

For the case **a)** a ring external optical cavity can be used which can reduce the laser power by a factor of 100-300.

For the case **b)** a linear cavity can be used which can reduce the laser power by a factor of 10 (or less).

The case **c)** needs the largest average power, but the minimum peak diode power.

Fig. 2.1 The experimentally observed charmonium states. The states labelled X, the nature of which is unknown, are not thought to be conventional charmonium states. Figure from Ref. [1]

Almost all charmonium states below DD threshold have been observed experimentally, but there are exotic X,Y,Z,X',X''states, $\Gamma_{\gamma\gamma}$ can help to understand their nature.

$b\bar{b}$

Fig. 2.2 The experimentally observed and theoretically expected bottomonium states. *Dashed lines* denote unobserved or unconfirmed states (an unconfirmed experimental candidate for the $\eta_b(2S)$ state has been observed by the Belle experiment [6]). Figure from Ref. [1]

Majority of bottomonium states below $B\bar{B}$ threshold have been observed experimentally, with exception of $\eta_b(3S)$, $h_b(3P)$ and most D-wave bottomonium. Many exotics states are observed (4-quark, molecules ??)

At e^+e^- colliders C^+ states above DD and BB thresholds are not observed yet because they are detected in radiative decays of Ψ and Υ , which become broad above the threshold (and radiative branching becomes very small).

In $\gamma\gamma$ -collisions these resonances will be produced directly. Their increased total width does not influence the production rate in $\gamma\gamma$ -collisions which is proportional to $\Gamma_{\gamma\gamma}$.

Comparison of the $\gamma\gamma$ factory and LHC for study $\gamma\gamma$ -physics in bb region

At $\gamma\gamma$ factory $\frac{dL_{\gamma\gamma}}{dW} \approx \frac{0.015 L_{ee}}{\text{GeV}}$

At LHC $\frac{dL_{\gamma\gamma}}{dW} \approx \frac{0.0025 \Delta\eta}{W} L_{pp} \approx \frac{0.0002 \Delta\eta}{\text{GeV}} L_{pp} \sim 3 \cdot 10^{-4} L_{pp}$ for $\Delta\eta = 1.5$

$$\frac{(dL / dW)_{\gamma\gamma\text{-factory}}}{(dL / dW)_{LHC}} \sim 50 \frac{L_{ee}}{L_{pp}}$$

Important:

in pp (or heavy ion-ion) collisions there is a huge background from diffractive processes (pomeron-pomeron, photon-pomeron) interactions that makes the study of $\gamma\gamma$ processes very problematic.

For example, at LHC in photon-pomeron(P) collision $C=-$ resonances are produced which are forbidden in $\gamma\gamma$ -collisions

P – Pomeron - multigluon state

final states are quite similar to those in $\gamma\gamma$ -collisions, only wider transverse momentum distribution

So, LHC can't compete in study of $\gamma\gamma$ -processes with a clean $\gamma\gamma$ -collider

Conclusion

- Photon colliders have sense as a very cost effective addition for e^+e^- linear colliders. However perspectives of high energy LCs are unclear already many years, photon colliders are considered as the second stage, so they can appear only in ~40 year
- It has sense to construct a smaller photon collider on the energy $W_{\gamma\gamma} \leq 12$ GeV (b,c regions), $\gamma\gamma$ physics here is very rich.
- Such $\gamma\gamma$ collider will be a nice place for application of modern outstanding accelerator, laser and plasma technologies (linacs (SC, plasma-based), low-emittance electron sources (incl. plasma), powerful laser systems, optical cavities). It does not need positrons and damping rings. The same electron linacs can be used simultaneously for XFELs.
