Field-emission investigations of micro-structured stainless steel ASTM 304

Tuesday 19 June 2018 18:00 (20 minutes)

Highly-alloyed chrome-nickel stainless steel is the most important material in vacuum technology. Especially in high and ultra-high vacuum technology it is used for vacuum chambers and components. One of the main research focuses before 2005 [1] was the study of parasitic field emission (FE) of specially treated stainlesssteel surfaces for applications in accelerator technology. The measured threshold field strength is about 25 \cdots 30 V/µm for 1 nA [2]. An important cause of field emission enhancement is the grain boundary structure. Therefore, stainless steel (ASTM 304 or 1.4301) was wet-chemical micro-structured and investigated with respect to field-emission properties. Some selected results are:

1. Threshold field strengths of micro-structured stainless steel are in the range of 7 V/µm for 1 mA (is better than [3], but CNT field emitter has $1 \cdots 2$ V/µm [4]).

2. For application as FE cathodes in vacuum components (cylindrical surfaces [1]), very large cathode arrays of a few cm^2 can be produced cost efficiently.

3. Very large cathode arrays with lower current density ($\leq 30\mu$ A/cm²) are field emitter with long-term stability. However, the main objective is the substitution of thermionic cathodes in vacuum electronic applications.
