Introduction to accelerators

Simone Gilardoni CERN-BE/ABP Simone.Gilardoni@cern.ch

SPEECH DELIVERED BY PROFESSOR NIELS BOHR

ON THE OCCASION OF THE INAUGURATION OF THE CERN PROTON SYNCHROTRON

ON 5 FEBRUARY, 1960

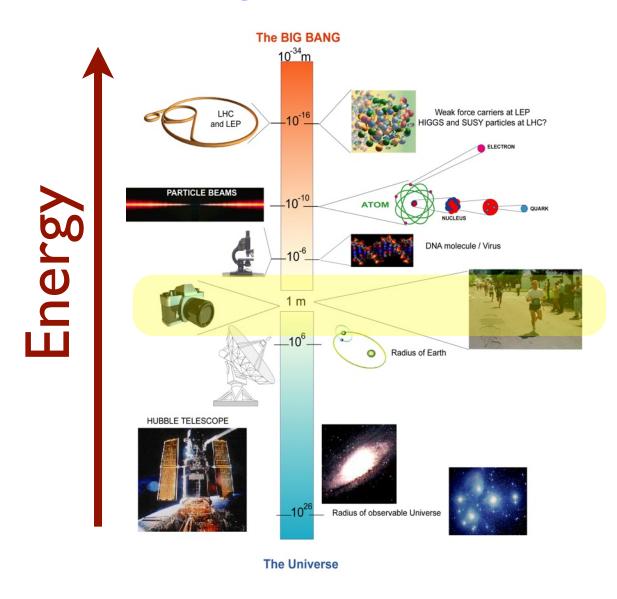

Press Release PR/56 12 February, 1960

It may perhaps seem odd that apparatus as big and as complex as our gigantic proton synchrotron is needed for the investigation of the smallest objects we know about. However, just as the wave features of light propagation make huge telescopes necessary for the measurement of small angles between rays from distant stars, so the very character of the laws governing the properties of the many new elementary particles which have been discovered in recent years, and especially their transmutations in violent collisions, can only be studied by using atomic particles accelerated to immense energies. Actually we are here confronted with most challenging problems at the border of physical knowledge, the exploration of which promises to give us a deeper understanding of the laws responsible for the very existence and stability of matter.

All the ingredients are there: we need high energy particles produced by large accelerators to study the matter constituents and their interactions laws. This also true for the LHC

Small detail... Bohr was not completely right, the "new" elementary particles are not elementary but mesons, namely formed by quarks

The right instrument for a given dimension

Wavelength of probe radiation should be smaller than the object to be resolved

$$\lambda \ll \frac{h}{p} = \frac{hc}{E}$$

Object Atom Nucleus Nucleon	Size 10 ⁻¹⁰ m 10 ⁻¹⁴ m 10 ⁻¹⁵ m	Energy of Radiation 0.00001 GeV (electrons) 0.01 GeV (alphas) 0.1 GeV (electrons)
Quarks	?	> 1 GeV (electrons)

Radioactive sources give energies in the range of MeV

Need accelerators for higher energies.

The typical energy of our life is eV So, how we can reach the energy/dimension of the big bang?

Interlude: a brief recall of energy scales

- WARNING: for purists or non-experts: Energy, Masses and Momentum have different units, which turn to be the same since c (speed of light) is considered equal to one.
 - Energy[GeV], Momentum [GeV/c], Masses [GeV/c²]
 (Remember golden rule, E=mc² has to be true also for units...)
- Just an as a rule of thumb: 0.511 MeV/c² (electron mass) corresponds to about 9.109 10-31 kg

An Example about energy scales: my cellular phone battery.

Voltage: 3.7 V

Height: 4.5 cm

proton mass ~ I GeV

To accelerate an electron to an energy equivalent to

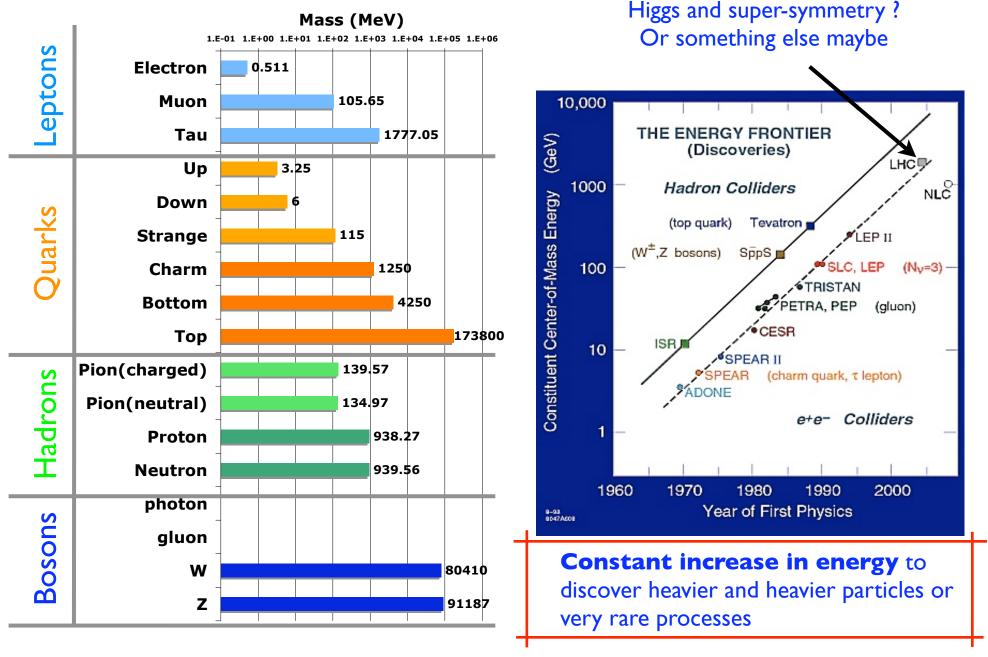

I GeV/3.7 eV = 270 270 270 batteries 270 270 270 batteries * 0.045 m ~ 12 000 000 m

12 000 000 m ~ THE EARTH DIAMETER

Obviously one has to find a smarter way to accelerate particles to high energies instead of piling up cellular phone batteries

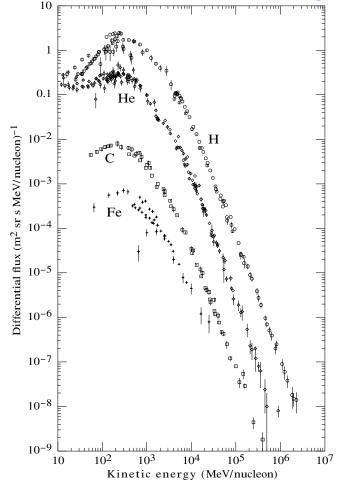

History/Energy line vs discovery

Obs: you can notice different particle species used in the different colliders electron-positrons and hadron colliders (either p-p as Tevratron, p-p as LHC)

Why particle accelerators?

- Why accelerators: need to produce under <u>controlled conditions</u> HIGH INTENSITY, at a CHOSEN ENERGY particle beams of GIVEN PARTICLE SPECIES to do an EXPERIMENT
- An experiment consists of studying the results of colliding particles either onto a fixed target or with another particle beam.

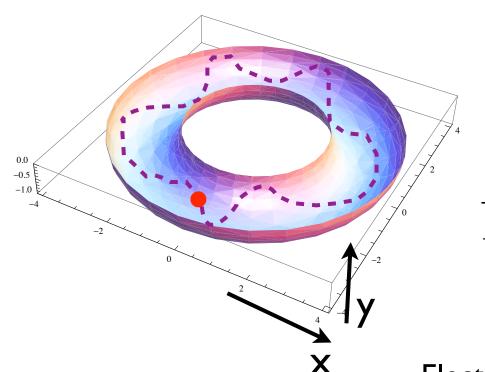

The cosmo is already doing collisions with different mechanisms:

while I am speaking about 66 10° particles/cm²/s are traversing your body, with this spectrum before being filtered by the atmosphere.

The universe is able to accelerate particles up to 106 MeV protons

How an accelerator works?

Goal: keep enough particles confined in a well defined volume to accelerate them

How? Lorentz Force!

$$\overline{F(t)} = q \left(\overline{E(t)} + \overline{v(t)} \otimes \overline{B(t)} \right)$$

Electric field accelerates particles

Particles of different energy (speed) behave differently

An **accelerator** is formed by a sequence (called **lattice**) of:

- a) Magnets
- b) Accelerating Cavity

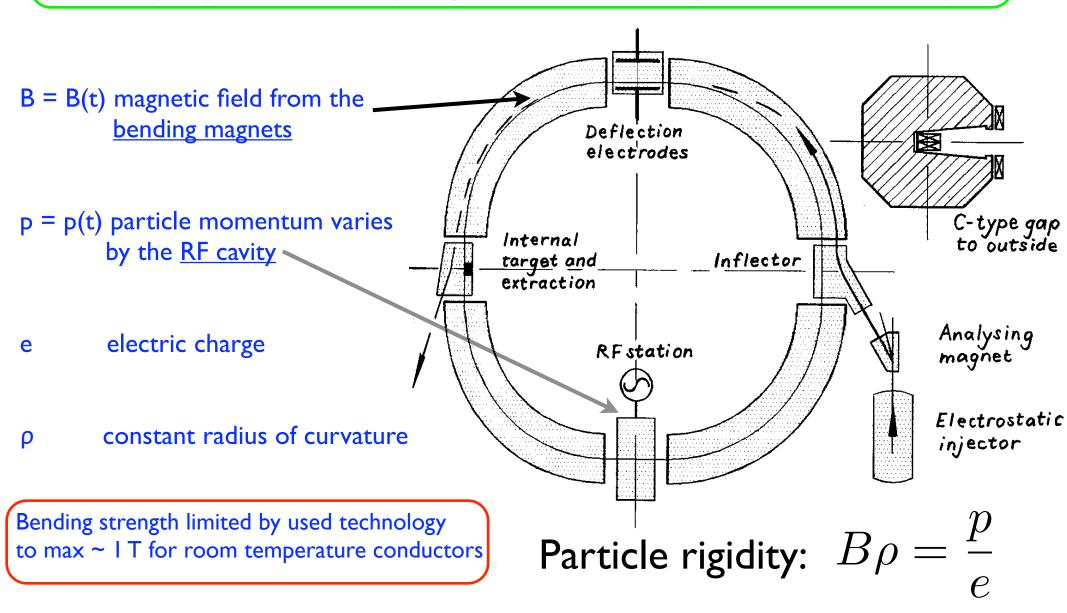

Magnetic field confines particles on a given trajectory

Synchrotron (1952, 3 GeV, BNL)

New concept of circular accelerator. The magnetic field of the bending magnet varies with time.

<u>As particles accelerate, the B field is increased proportionally.</u>

The frequency of the accelerating cavity, used to accelerate the particles, has also to change.

Dipole

Force given by the vertical magnetic field compensate the centrifugal force to keep the particles on the central trajectory, i.e. in the center of the beam pipe.

Once the beam accelerates, the magnetic field is increased synchronously

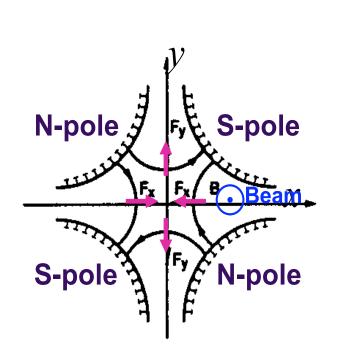

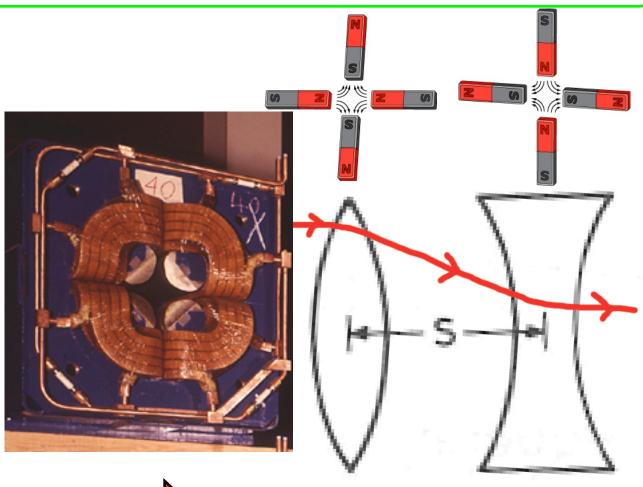

Synchrotrons: strong focusing machine

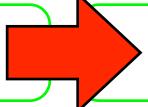

Dipoles are interleaved with quadrupoles to focus the beam.

Quadrupoles act on charged particles as lens for light. By alternating focusing and defocusing lens (Alternating Grandient quadrupoles) the beam dimension is kept small (even few mum²).

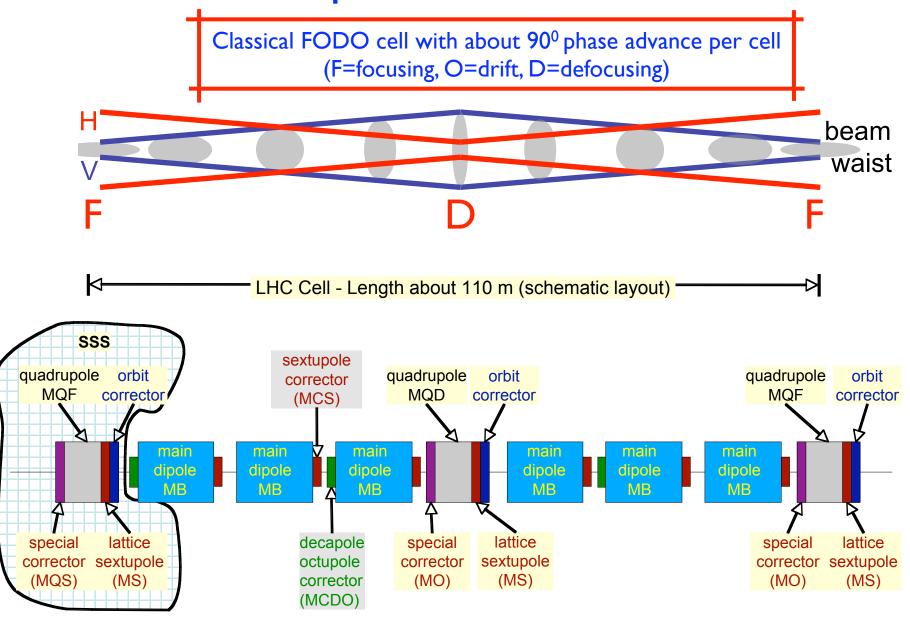

B field is focusing in one plane but defocusing in the other.

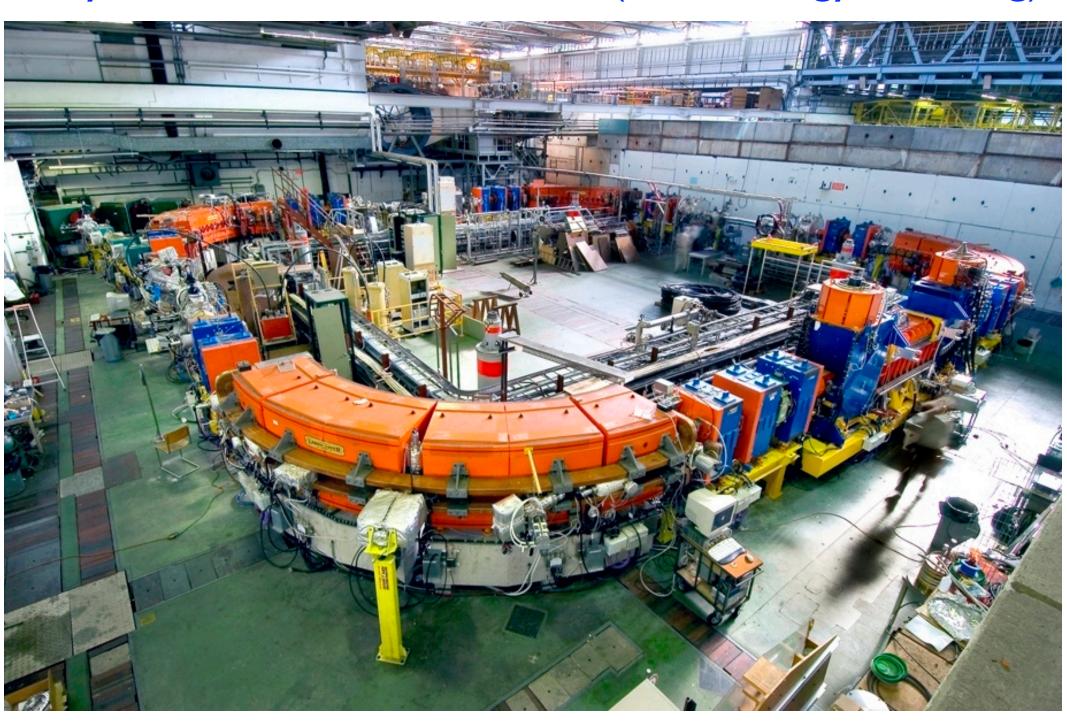

Typical lattice is FODO, focusing-drift-defocusing

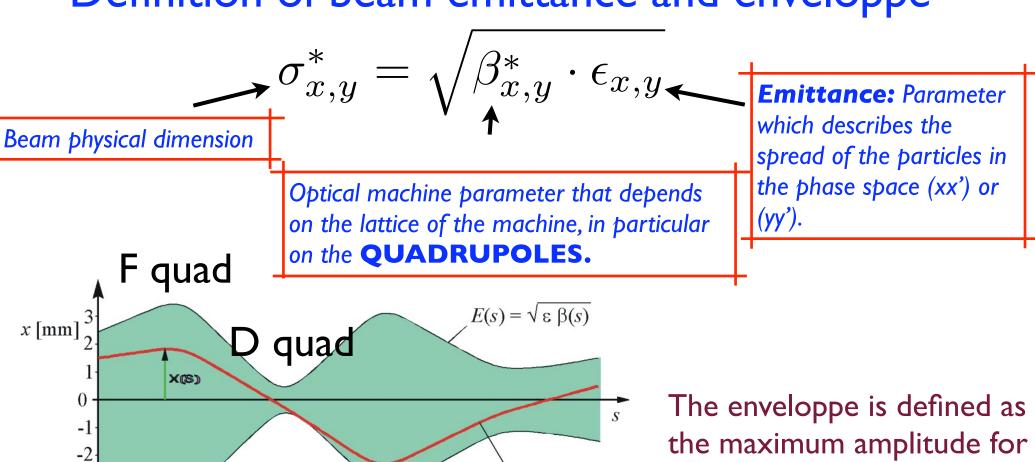

An example of a lattice: LHC cell

A synchrotron in a view: LEIR (Low Energy Ion Ring)

Definition of beam emittance and enveloppe

Teilchenbahn

-3

-1 -2

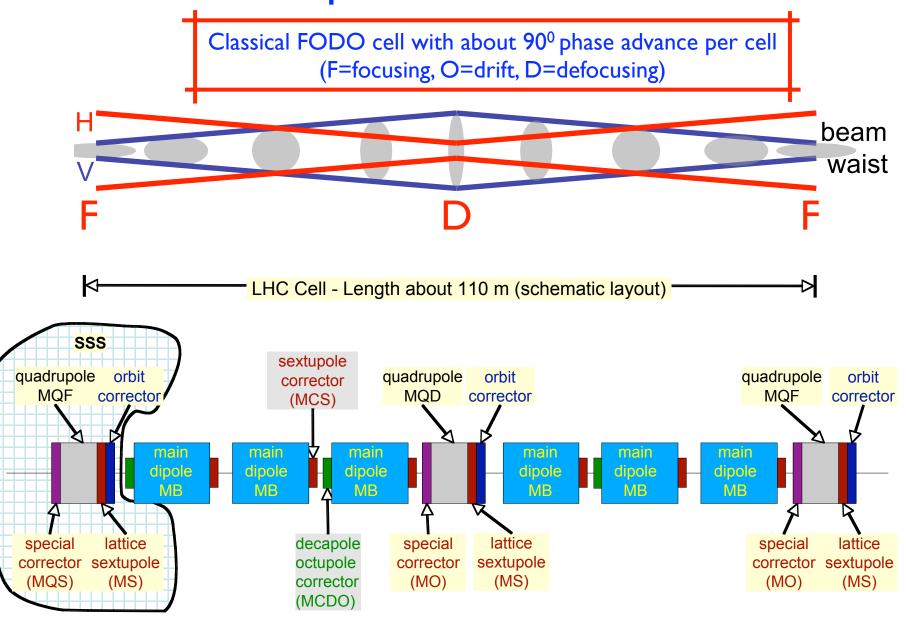

-3

x [mm]

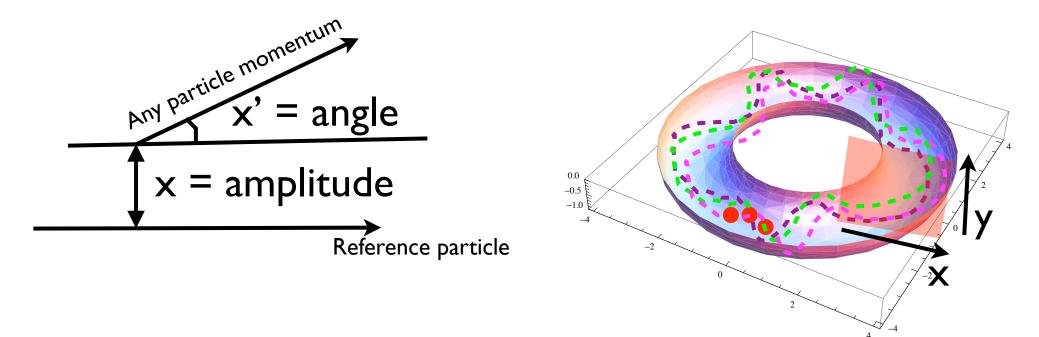

Enveloppe

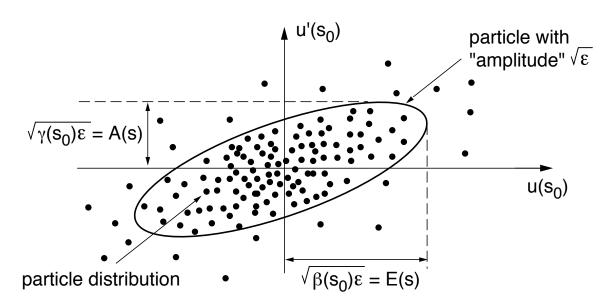

The enveloppe is defined as the maximum amplitude for which the particle remains in the machine vacuum chamber.

An example of a lattice: LHC cell

Our reference frame: xx', the phase space

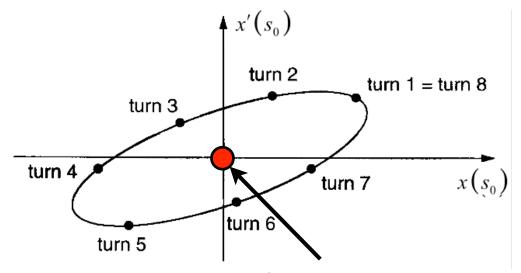

The space occupied in the xx' (or yy') plane by the beam at a given position in the machine is defined as Emittance

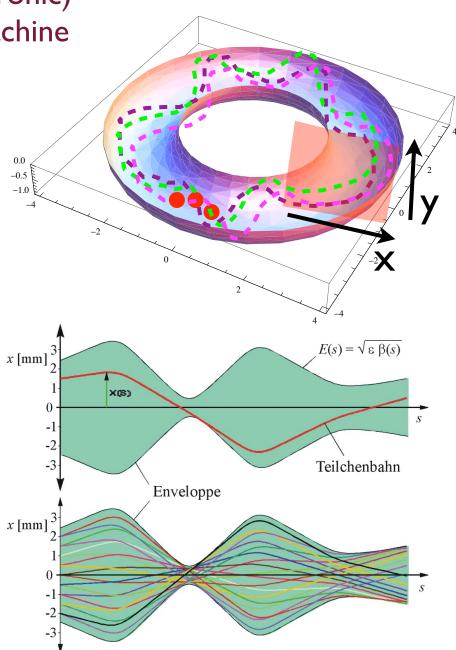

Tune

Tune: number of oscillations (called betatronic) in the xx' plane a particle does in one machine turn.

The tune depends on the quadrupoles setting

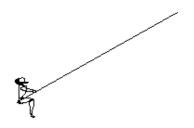

Reference particle

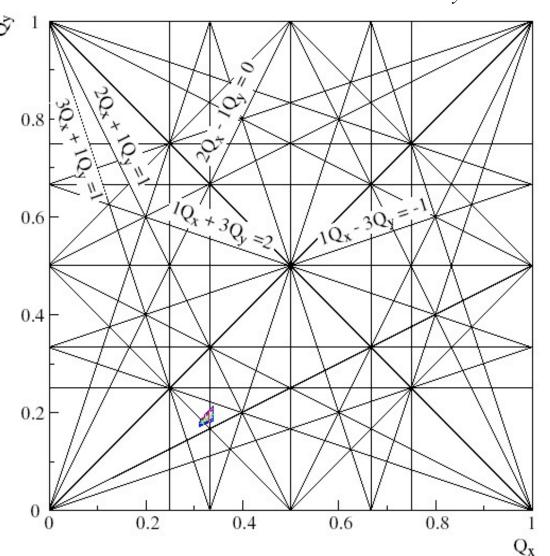

Tune and resonances

Like on a "balançoire", to keep the oscillations bounded in amplitude, one has to avoid to excite the beam in a resonant way.

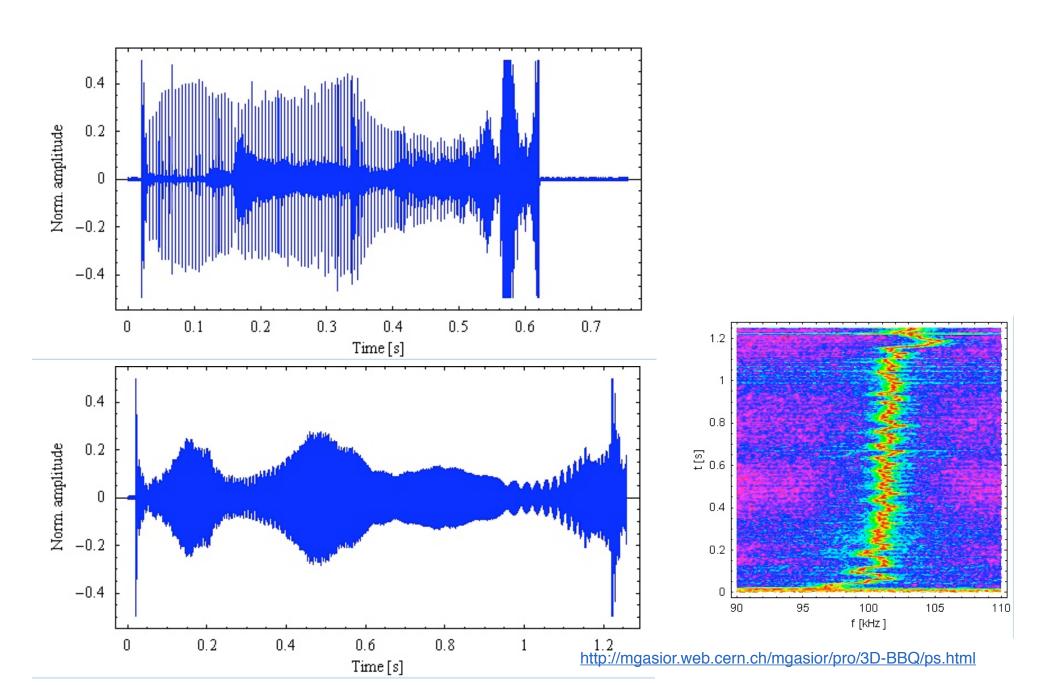

The tune has to be far away from some values, like exciting the beam with the same force at each turn

To avoid $M Q_x + N Q_y = P$

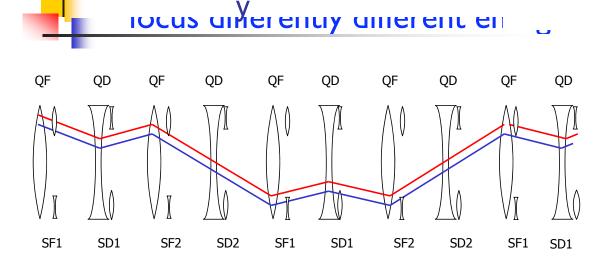

Tune: number of betatron oscillation in the transverse plane

Chromaticity

- If the energy of a particle is different from the energy of the reference particle, the quadrupoles will focus less or more, so the tune will change according to the energy, as if the accelerator suffer from ASTIGMATISM (or MIOPHY).
 - This is defined as CHROMATICITY
 - Since one want to avoid crossing resonances, the CHROMATICITY has to be kept small and corrected.
 - This can be done by using S

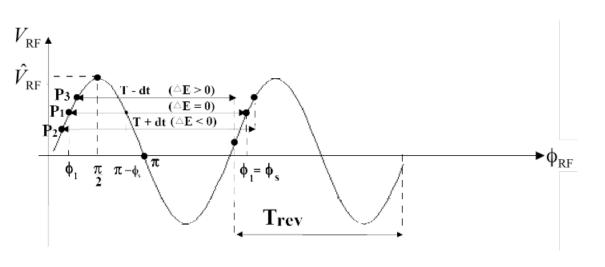

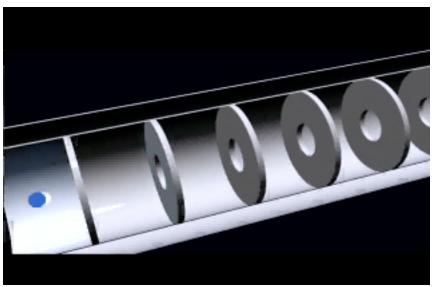

Acceleration

- Particles are accelerated by an RF (radio frequency) electric field which is confined in cavities.
- The electric field varies in time as a sinus wave in such a way, that at each revolution, the particle comes back at the RF to see the acceleration.

$$\Rightarrow \Delta E_1 = e \hat{V}_{RF} \sin \phi_1$$

Longitudinal focusing

del E (MeV)

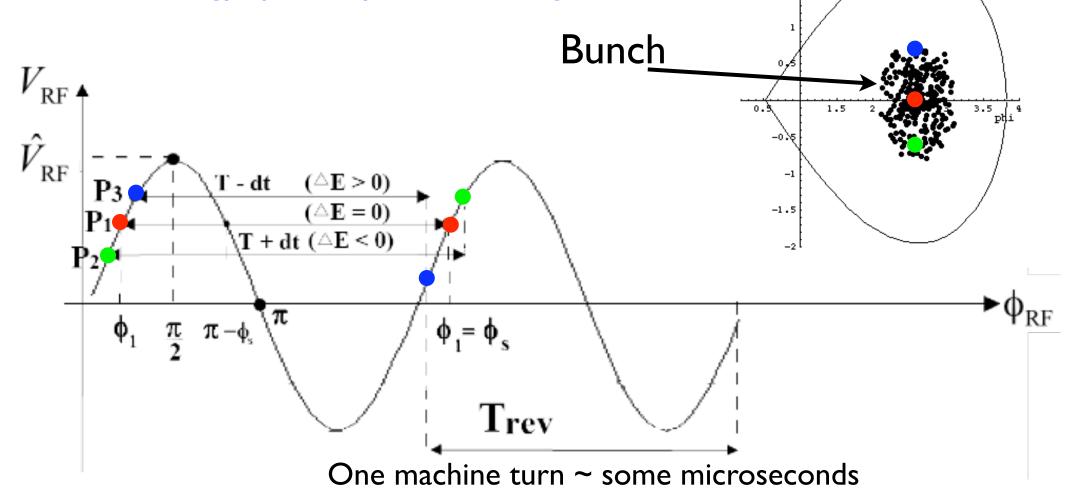

turns= 0

Particles are confined within a range in phase and energy called
 BUCKET and are grouped into bunches.

Bucket

• The bunch length depends on the RF frequency.

The energy spread by the RF voltage

Longitudinal focusing

del E (MeV)

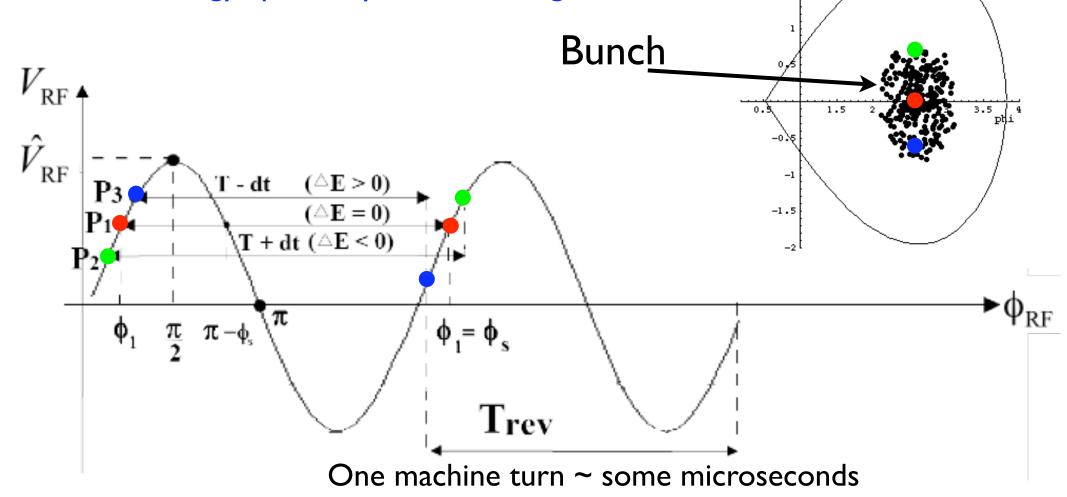

turns= 0

Particles are confined within a range in phase and energy called
 BUCKET and are grouped into bunches.

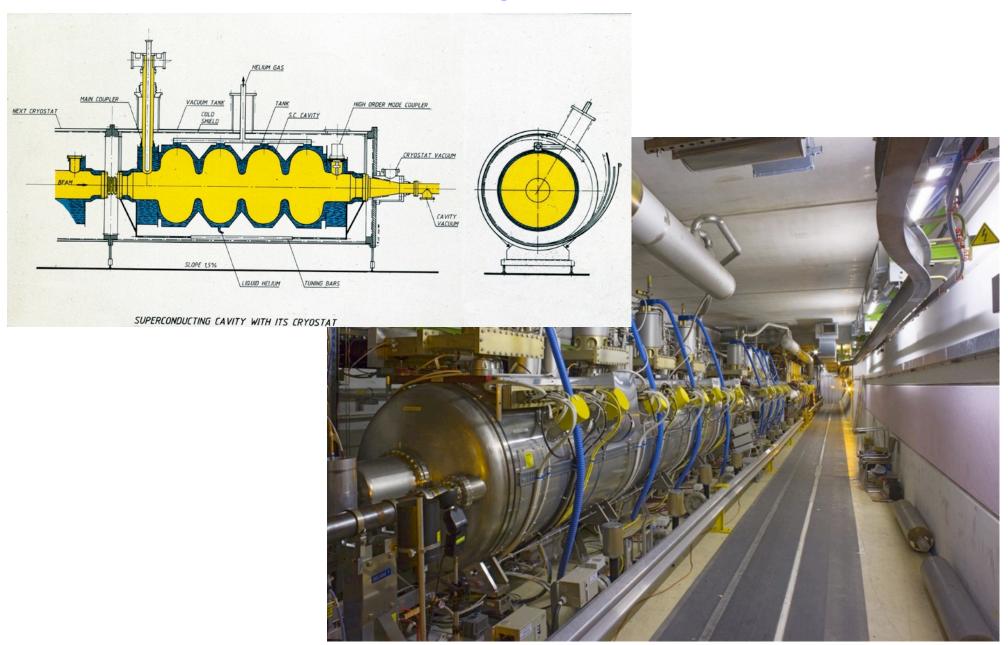

Bucket

• The bunch length depends on the RF frequency.

The energy spread by the RF voltage

RF system

First part summary

- Dipoles bend charged particles in the accelerator
- Quadrupoles focus particles and define the beam tune
- Sextupoles keep the tune spread (Chromaticity) due to an energy spread small
- RF cavities accelerate the beam
- The emittance is the space occupied by the particles in the xx' plane
- The enveloppe is defined by the quadrupoles via the beta function

What is the LHC?

LHC: Large Hadron Collider

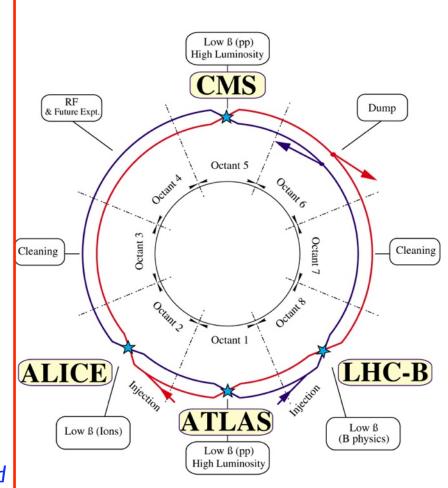

LHC is a collider and synchrotron storage ring: ILC is a collider but is not a synchrotron storage ring

Large: high energy needs large bending radius due to the maximum magnetic field existing technology can produce **26.7 km circumference**

Hadrons: p p collision \Rightarrow synchrotron radiation and discovery machine.

Collider: particles are stored in two separated rings which are <u>synchrotrons</u>, and accelerated from injection energy (450 GeV) to 7 TeV. At 7 TeV the two beams are forced to cross in collision points to interact.

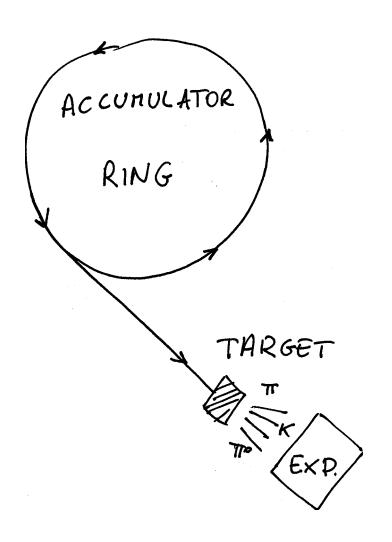

The beams are stored at 7 TeV for few 10 h to produced collisions. When the intensity is too low, the two rings are emptied and the process of injecting, accelerating, storing and colliding is restarted, until one finds the higgs or supersymmetry... then one needs a bottle of Champaign and a nobel price ...

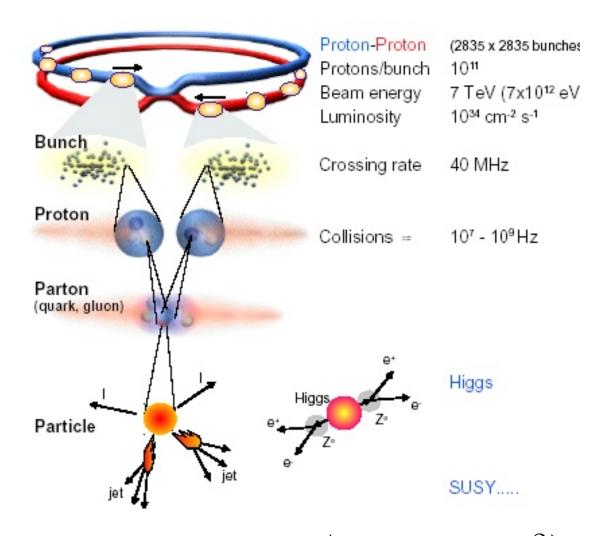

Different approaches: fixed target vs collider

Fixed target

Storage ring/collider

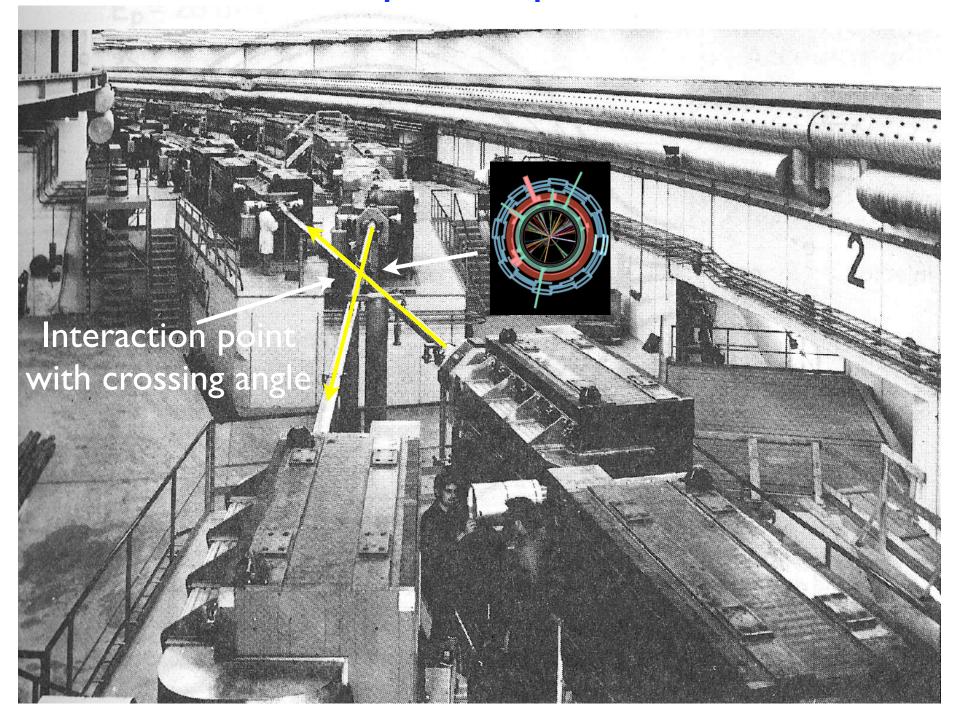

$$E_{CM} = \sqrt{2\left(E_{beam}mc^2 + m^2c^4\right)}$$

$$E_{CM} = 2\left(E_{beam} + mc^2\right)$$

This usually is defined as \sqrt{s}

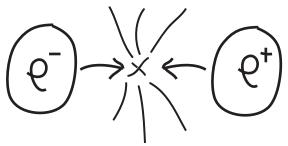

ISR, the first proton-proton collider

The proper particle for the proper scope

Electrons (and positrons) are (so far) point like particles: no internal structure

Protons (and antiprotons) are formed by quarks (uud) kept together by gluons

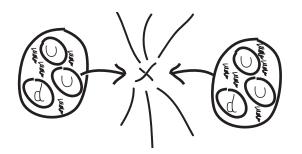

The energy of the collider, namely two times the energy of the beam colliding is totally transferred into the collision

Ecoll= EbI + Eb2 = 2Eb = 200 GeV (LEP)

<u>Pros:</u> the energy can be precisely tuned to scan for example, a mass region.

Precision measurement (LEP)

<u>Cons:</u> above a certain energy is no more possible to use electrons because of too high <u>synchrotron radiation</u>

The energy of each beam is carried by the proton constituents, and it is not the entire proton which collides, but one of his constituent

Ecoll (about 2 TeV at LHC) < 2 Eb (14 TeV)

Pros: with a single energy possible to scan different processes at different energies.

Discovery machine (LHC)

Cons: the energy available for the collision is lower than the accelerator energy

Synahhoatonnraddiationn

Radiation emitted by charged particles accelerated longitudinally and/or transversally

Power radiated per particle goes like:

$$P = \frac{2c \times E^4 \times r_0}{3\rho^2 \left(m_0 \times c^2\right)^3}$$

4th power of the energy

(2nd power)-1 of the bending radius

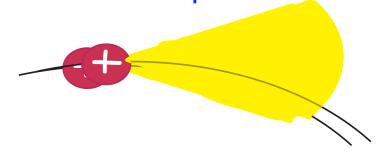

(4th power) -1 of the particle mass $r_0 r = \frac{q^2 q^2}{4\pi \sqrt[4]{2} powed} c^2$ particle classical radius ρ particle bending radius

Energy lost per turn per particle due to synchrotron radiation:

e-
$$\approx$$
 some GeV (LEP)

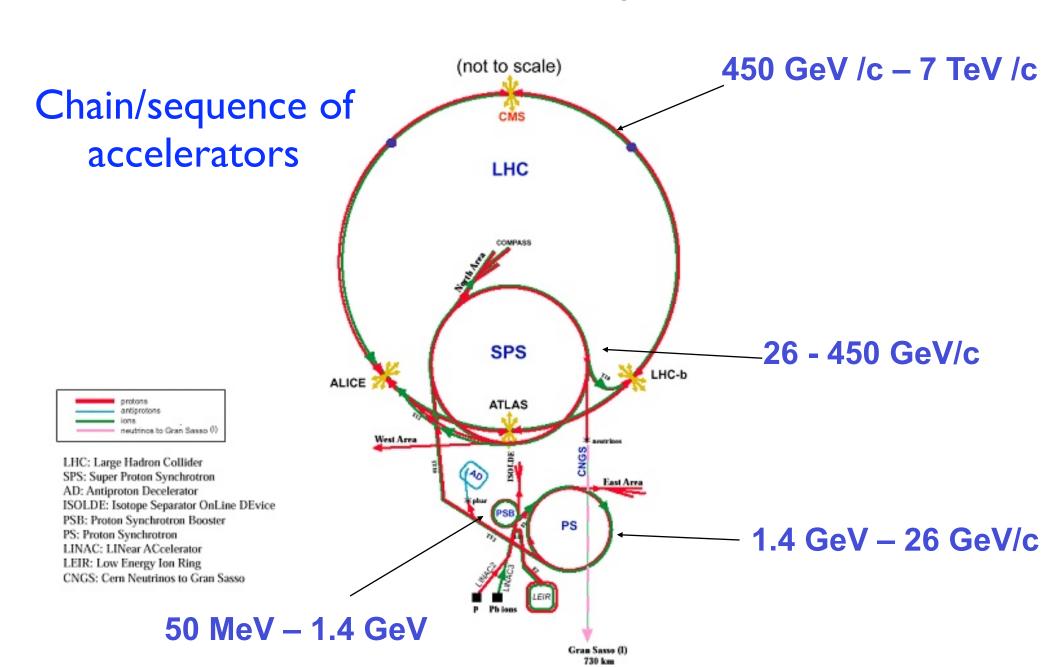

$$p \approx some keV (LHC)$$

We must protect the LHC coils even if energy per turn is so low

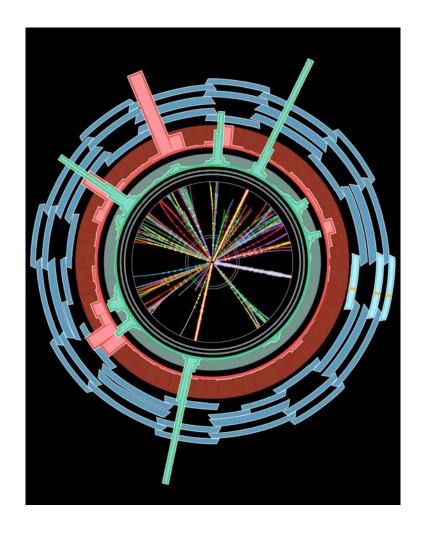

Power lost per m in dipole: <u>some W</u>
Total radiated power per ring: <u>some kW</u>

CERN accelerator complex overview

Basically the injector chains brings you ...

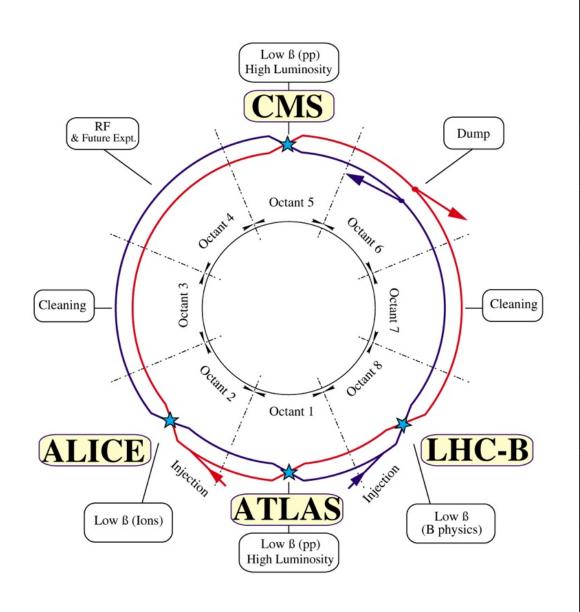

from nearly a bottle of hydrogen

to a little bit before this

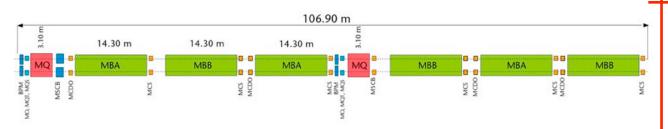

LHC layout and few parameters

Particle type	protons (heavy ions, Pb82+)	
Energy	450 GeV (injection) 7 TeV (collision energy) 2,75 TeV/u (ions collision)	
Circumference	26658 m	
Revolution frequency	11,245 kHz	
Number of rings	l (two-in-one magnet design)	
Number of accelerators	2 (2 independent RF system)	
Interaction Points (IP) or Collision Points or Low beta insertions	4 (ATLAS, CMS, ALICE, LHCb)	
Cleaning insertions or collimation insertions	2	
Beam dump extractions	2	
RF insertion	I	

LHC cost ~1,899.64 MEUR, without the tunnel... ONE F1 season costs about 1,500 MEUR

Basics components of the LHC

Regular ARC

MQ: Lattice Quadrupole MO: Landau Octupole MQT: Tuning Quadrupole

MQS: Skew Quadrupole

MSCB: Combined Lattice Sextupole (MS) or skew sextupole (MSS) and Orbit Corrector (MCB)

BPM: Beam position monitor MBA: Dipole magnet Type A

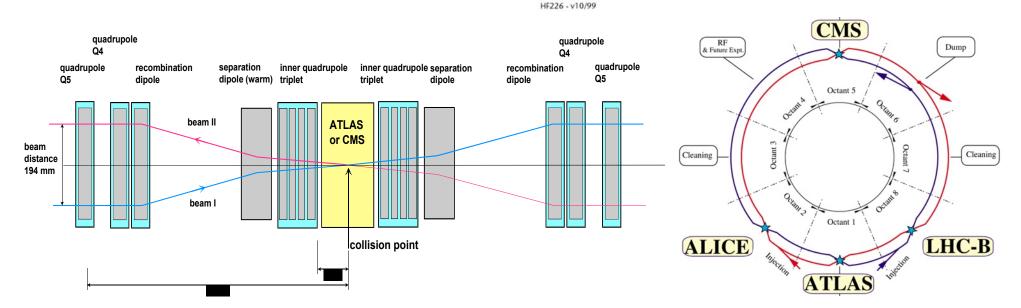

MBB: Dipole magnet Type B

MCS: Local Sextupole corrector

MCDO: Local combined decapole and octupole corrector

Synchrotron:

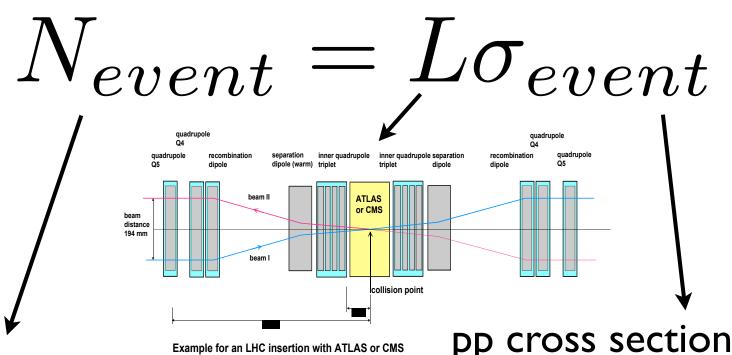

- a) dipoles to bend particles with increasing field vs time i.e. vs energy
- b) quadrupoles to focus the beam and keep it in the aperture
- c) interaction point with final focusing to collide the two beams

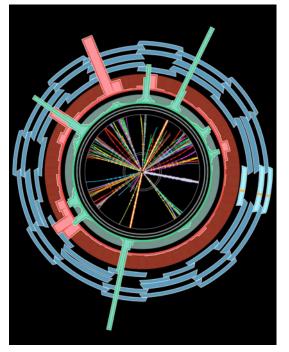

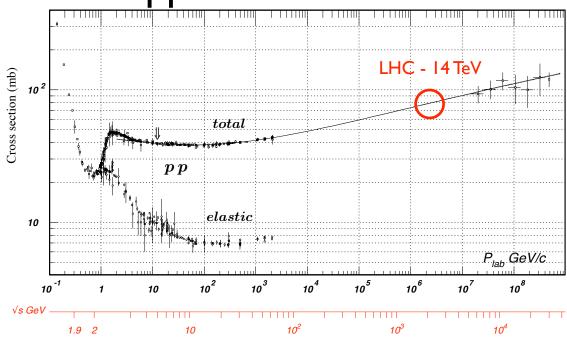

Example for an LHC insertion with ATLAS or CMS

Interaction points

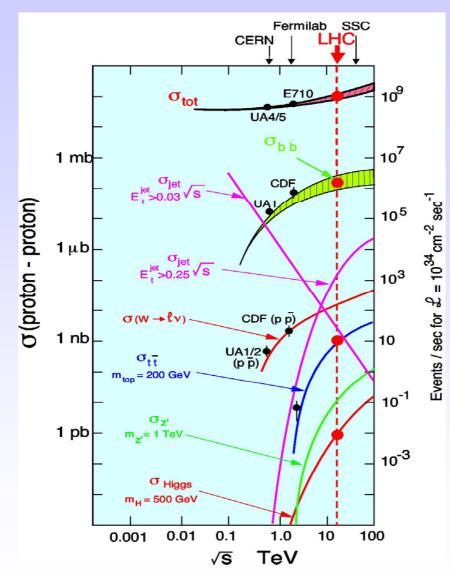

Luminosity

Cross Sections and Production Rates

Rates for L = 10^{34} cm⁻² s⁻¹: (LHC)

The LHC optics in one slide

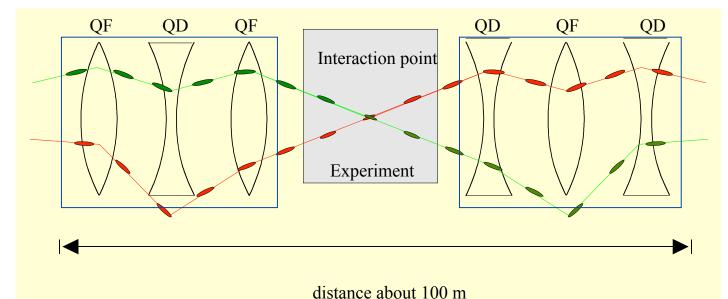

Crossing angle

Angle @ IP to avoid that the 2808 bunches collides in other places than the IP in the LSS.

~ 30 unwanted collision per crossing

$$F = 1/\sqrt{1 + \left(\frac{\theta_c \sigma_z}{2 \cdot \sigma^*}\right)^2}$$

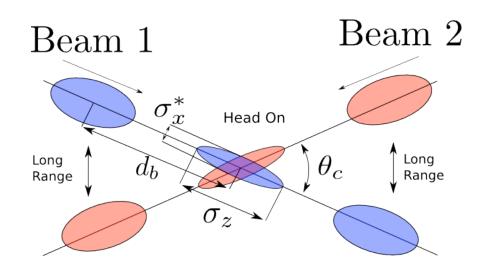

Θс	crossing angle	285 µrad
σ _z	RMS bunch length	7.55 cm
σ*	RMS beam size (ATLAS-CMS)	16.7 μm
F	L reduc. Factor	0.836

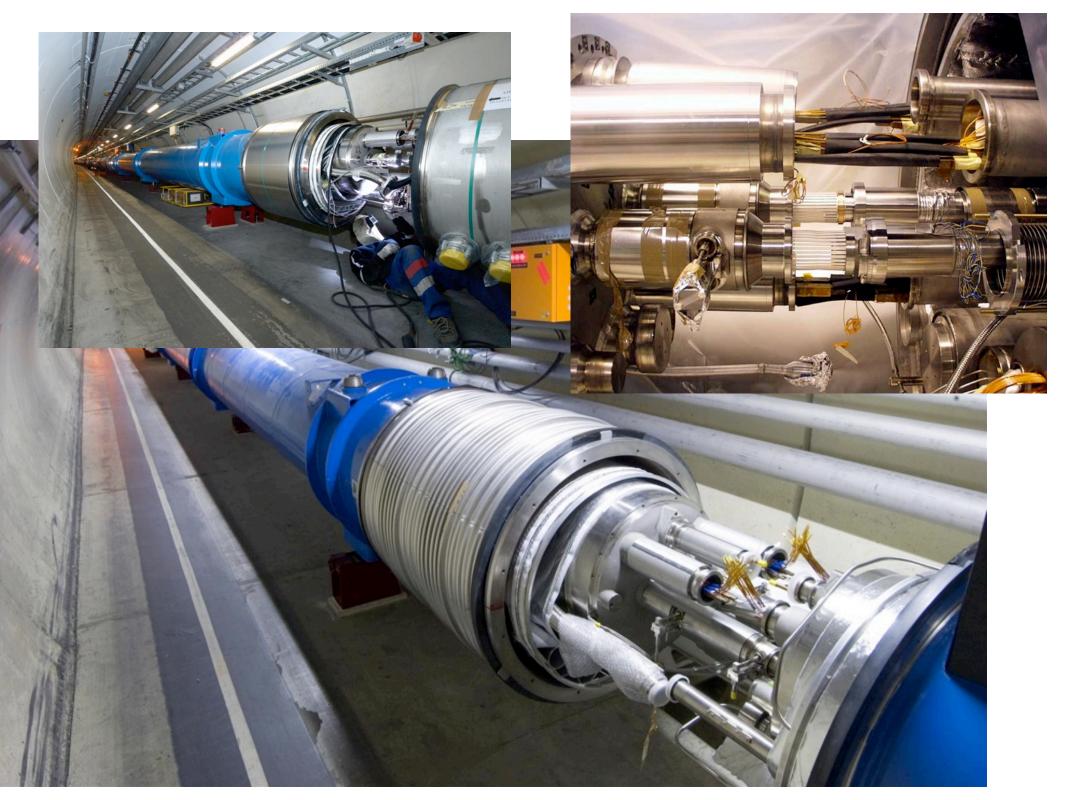

Few LHC numbers ...

$$L = \frac{N^2 \cdot f \cdot n_b}{4\pi \cdot \sigma_x^* \cdot \sigma_y^*} \cdot F$$

$$F = 1/\sqrt{1 + \left(\frac{\theta_c \sigma_z}{2 \cdot \sigma^*}\right)^2}$$

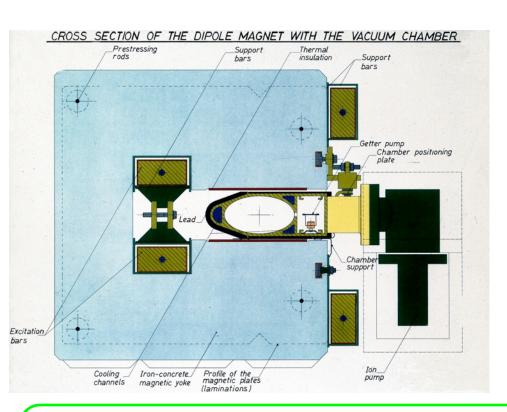

Luminosity	I 10 ³⁴ /cm ² /s (IPI IP5)
Particle per bunch	1,15 1011
Bunches	2808
Revolution frequency	11,245 kHz
Crossing rate	40 MHz
Nomalised Emittance	3.75 µm rad
β-function at the collision point	0.55 m
RMS beam size @ 7 TeV at the IPI-5	16.7 μm
Circulating beam current	0.584 A
Stored energy per beam	362 MJ

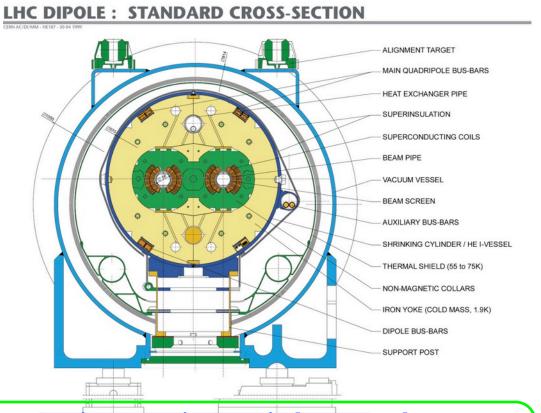

LEP vs LHC: Magnets, a change in technology

Bending Field \rightarrow p(TeV) = 0.3 B(T) R(Km) (earth magnetic field is between 24 mT and 66 mT)

Tunnel R \approx 4.3 Km LHC 7 TeV \rightarrow B \approx 8.3 T \rightarrow <u>Superconducting coils</u> LEP 0.1 TeV \rightarrow B \approx 0.1 T \rightarrow **Room temperature coils**

Protons can go up in energy more than electrons because they **emit less synchrotron radiation.** Bending (dipoles) and focusing (quadrupoles) strengths require high magnetic fields generated by superconductors

INTERLUDE: THE TERMINATOR-3 ACCELERATOR

We apply some concepts to the accelerator shown in Terminator-3 [Columbia Pictures, 2003]

Estimation of the magnetic field

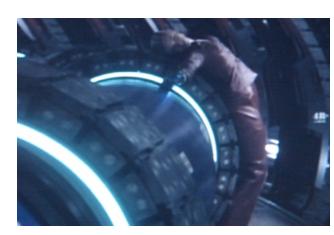

- Energy = 5760 GeV
- Radius ~30 m
- Field = $5760/0.3/30 \sim 700 \text{ T}$ (a lot!)

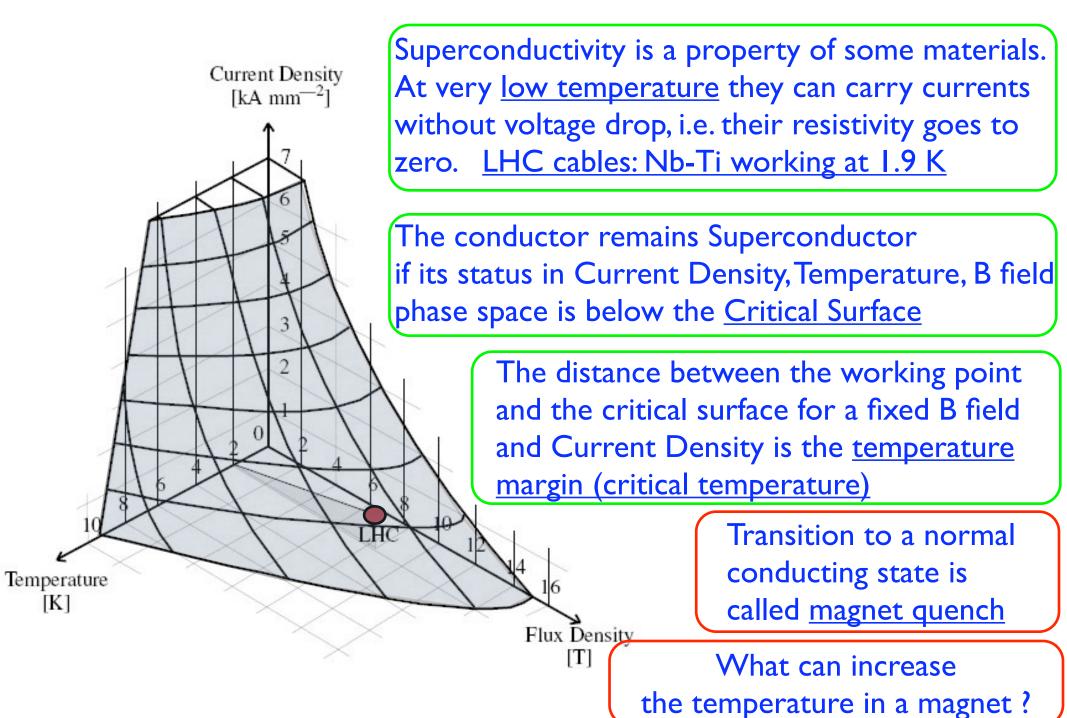

Energy of the machine (left) and size of the accelerator (right)

- Why the magnet is not shielded with iron?
 - Assuming a bore of 25 mm radius, inner field of 700 T, iron saturation at 2 T, one needs 700*25/2=9000 mm=9 m of iron ... no space in their tunnel!
 - In the LHC, one has a bore of 28 mm radius, inner field of 8 T, one needs 8*25/2=100 mm of iron
- Is it possible to have 700 T magnets ??

A magnet whose fringe field is not shielded

Very, very short introduction to Superconductivity for accelerators

Beam losses can eat the temperature margin because of energy deposition

Limit of accepted losses: ~ 10 mW/cm³ to avoid $\Delta T > 2$ K, the temperature margin

How much is 10 mW/cm³?

A fluorescente (known as neon) tube can be typically 1.2 m long with a diameter of 26 mm, with an input power of 36 W.

This makes a power density of about 56 mW/cm³.

The power of a neon tube can quench about 5 LHC dipoles at collision energy.... because one does not need 10 mW/cm³ for the entire volume of a magnet, but for about 1 cm³.

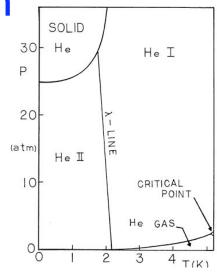

If you do the same basic computation with a normal 100 W resistive bulbs is even worst

When something goes wrong.... bad quench...

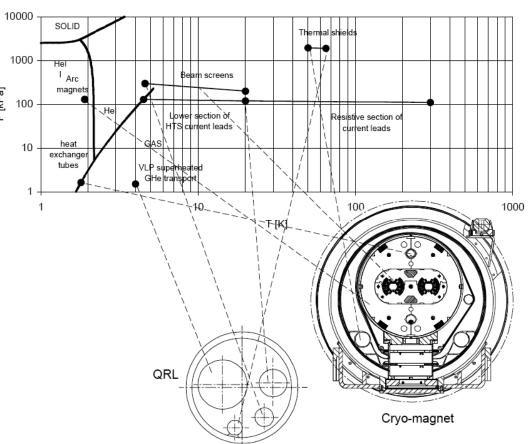

Which coolant? Liquid superfluid helium

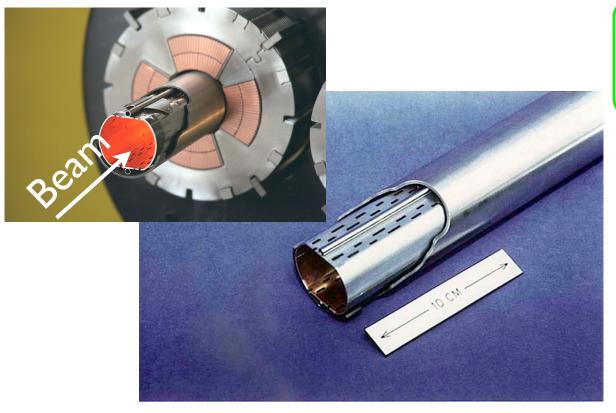

LHC cryogenics will need 40,000 leak-tight pipe junctions. 12 million litres of liquid nitrogen will be vaporised during the initial cooldown of 31,000 tons of material and the total inventory of liquid helium will be 700,000 l (about 100 tonnes)

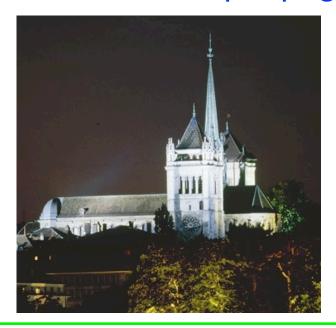

LHC beam screen with cooling pipes

Atmosphere pressure = 750 Torr Moon atmospheric pressure = 5 10⁻¹³ Torr Beam screen to protect Superconducting magnets from Synchrotron radiation.

Holes for vacuum pumping

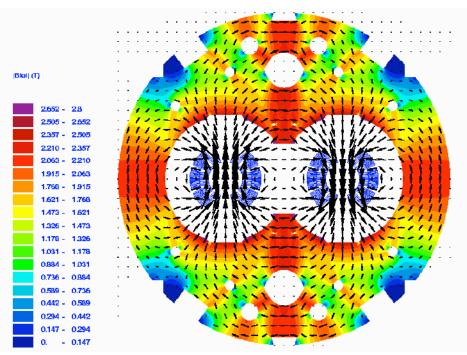

Vacuum required to avoid unwanted collision far from the IPs and decrease the Luminosity

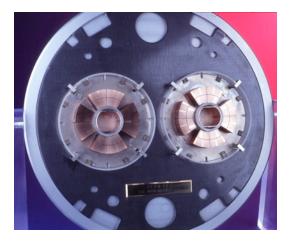

Typical vacuum: 10⁻¹³ Torr

There is ~6500 m³ of total pumped volume in the LHC, like pumping down a cathedral.

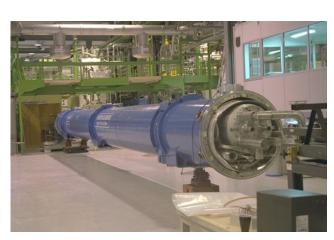

Two-in-one magnet design

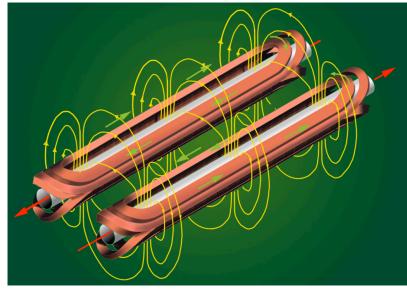

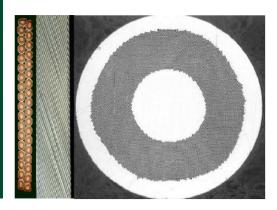

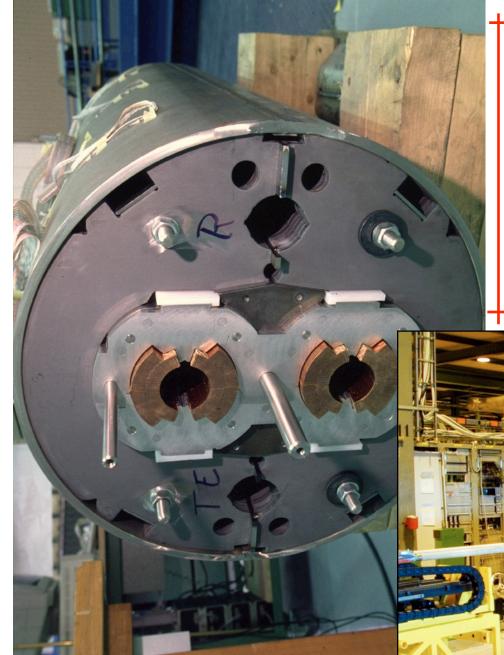

The LHC is one ring where two accelerators are coupled by the magnetic elements.

Nb -Ti superconducting cable in a Cu matrix

At 7 TeV:

 $I_{\text{max}} = 11850 \text{ A Field} = 8.33 \text{ T}$

Stored energy= 6.93 MJ

Weight = 27.5 Tons

Length = 15.18 m at room temp.

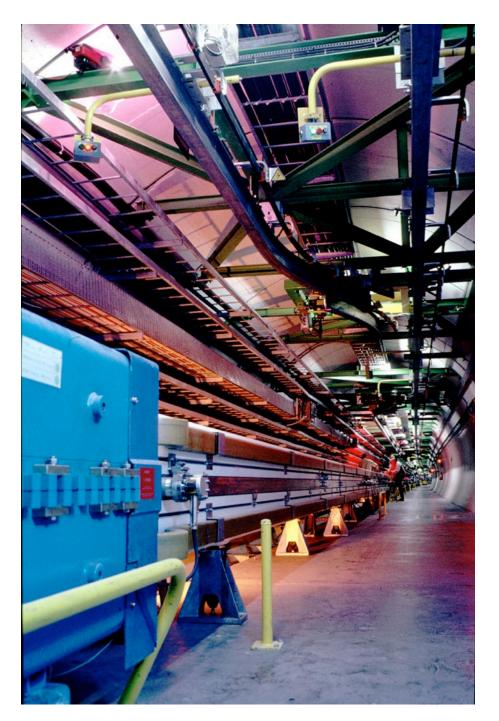

Length (I.9 K)=15 m - \sim 10 cm

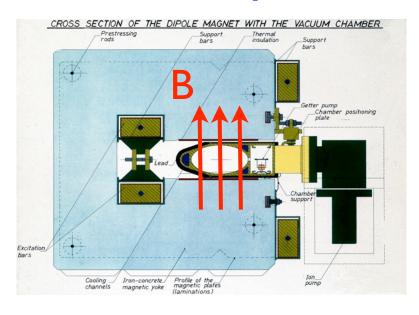

Test bench for magnetic measurements at 1.9 K

From LEP to the LHC, iron-concrete yoke ...

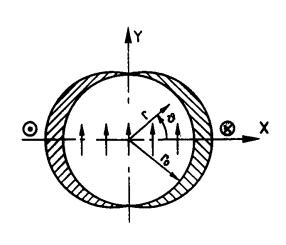

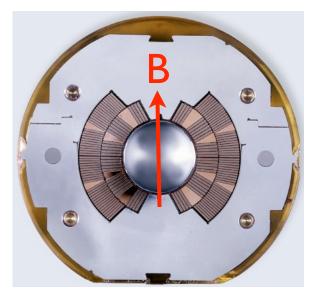

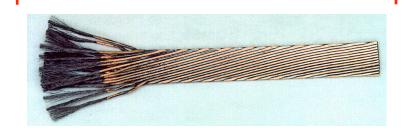

$Cos\theta$ coil of main dipoles

<u>Cos nϑ</u>

A 2D $\cos\theta$ current distribution generates a quasi-perfect vertical field in the aperture between the two conductors.

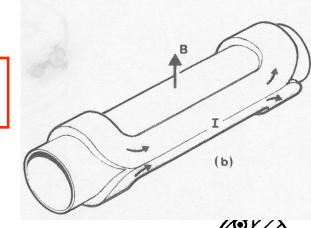

$$I = I_o \cos \vartheta$$

$$B_{\vartheta} = \frac{\mu o \ I_o}{2 \ r_o} \cos \vartheta \qquad B_x = o$$

$$B_{\vartheta} = \frac{\mu o \ I_o}{2 \ r_o} \sin \vartheta$$

$$B_x = o$$

$$B_y = \frac{\mu o \ I_o}{2 \ r_o}$$

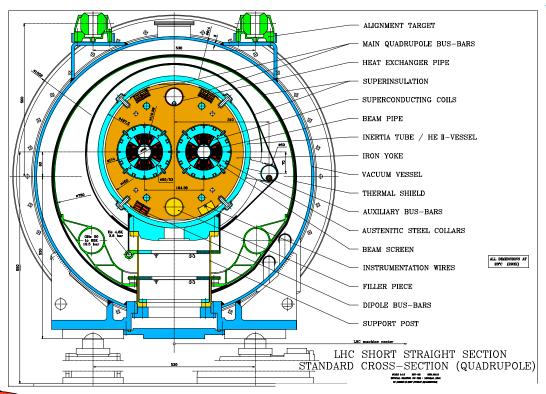

Dipolar Vertical field

Quadrupole

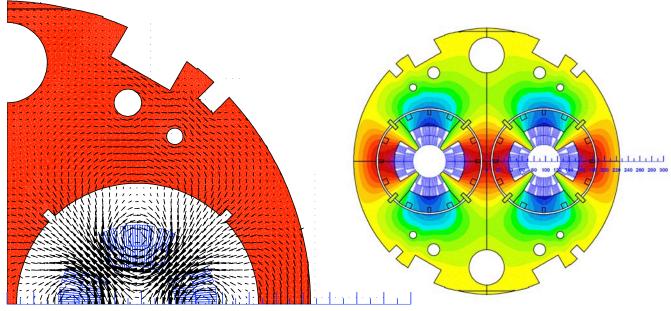

Quadrupoles are also two-in one

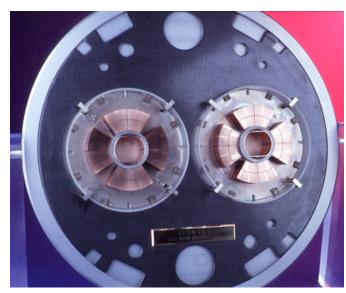

At 7 TeV:

 $I_{max} = 11850 A$ Field=225 T/m

Weight = 6.5 Tons Length = 3.1 m

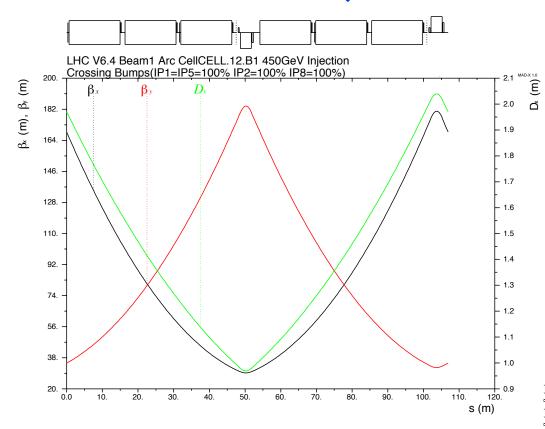

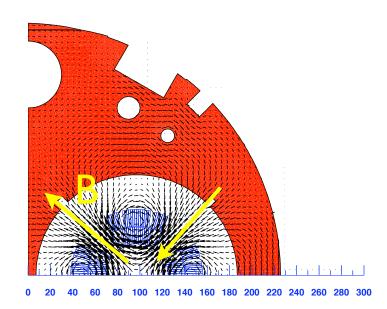

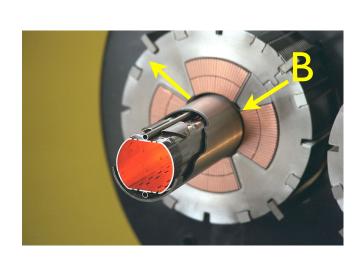

Quadrupoles being assembled before installation

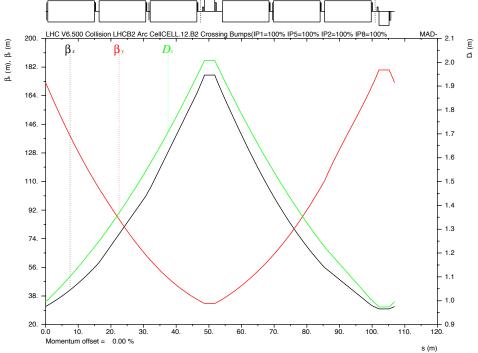

Arc cell at injection for beam 1 and beam 2

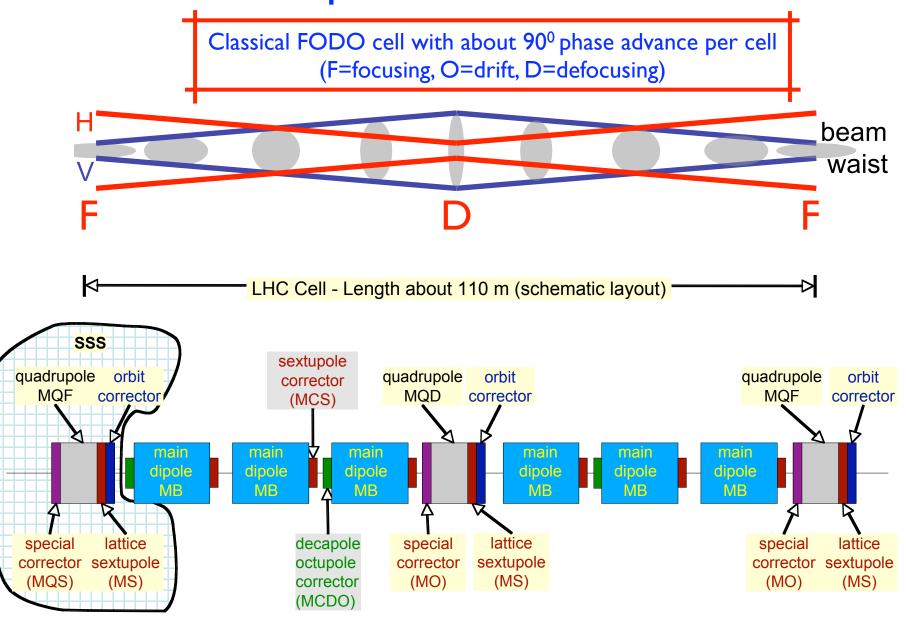

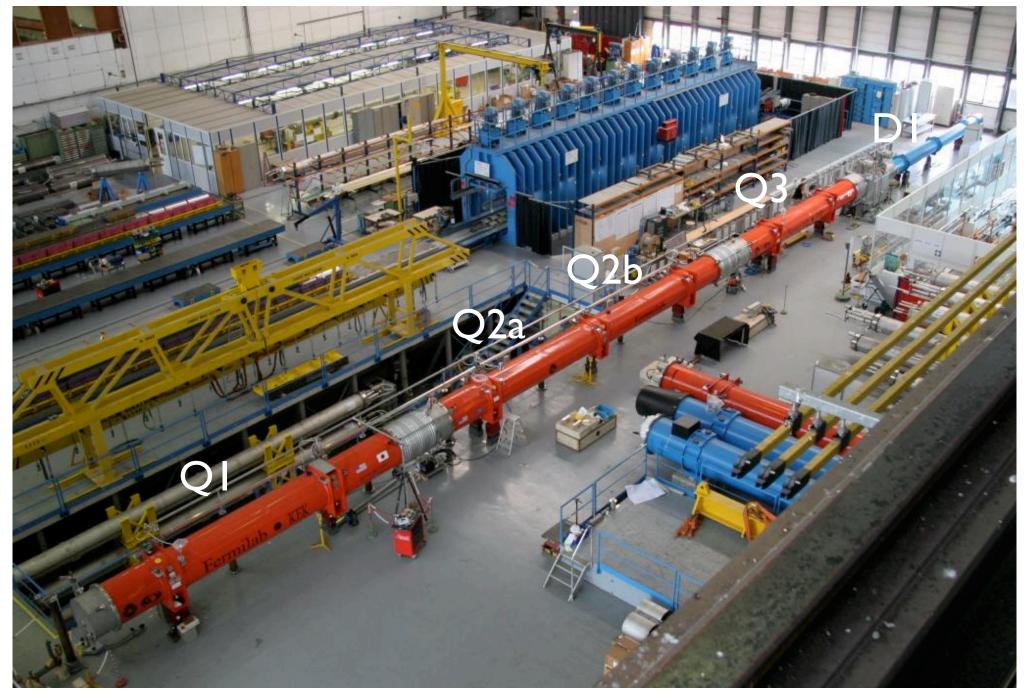

An example of a lattice: LHC cell

One LHC test CELL on surface

Triplets before lowering in the tunnel

Working point choice

Tune: number of betatron oscillations in the x-x' (Qx) or y-y' (Qy) plane per machine turn.

An integer number in Qx or Qy correspond to a 2π rotation in the phase space. Not interesting in term of resonance instabilities.

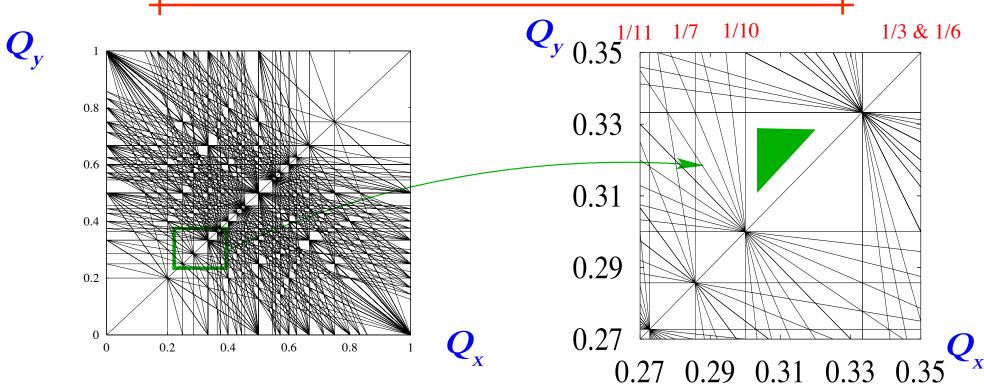

Usually fractional tune is quoted, meaning what rest of the tune after subtracting the integer part. From previous experience (Hera, Tevatron)

Avoid resonances n+m < 12

Working point \rightarrow Qx and Qy. LHC working point: $Q_x=64.28, Q_v=59.31$

Choose region of (Qx,Qy) with enough free space from resonances

LEP sextupole

LHC: the issue of stored beam energy

Why do we have to protect the machine?

Why do we have to protect the machine?

Total stored beam energy at top energy (7 TeV), nominal beam, 334 MJ (or 120 kg TNT)

Nominal LHC parameters: 1.15 1011 protons per bunch

2808 bunches

0.5 A beam current

British aircraft carrier:

HMS Illustrious and Invincible weigh 20,000 tons all-up and fighting which is 2×10^7 kg.

Or the USS Harry S. Truman (Nimitz-class) - 88,000 tons.

Energy of nominal LHC beam = 334 MJ or $3.34 \times 10^8 \text{ J}$

which corresponds to the aircraft carrier navigating at v=5.8 m/s or 11.2 knots (or around 5.3 knots if you're an American aircraft carrier)

So, what if something goes wrong?

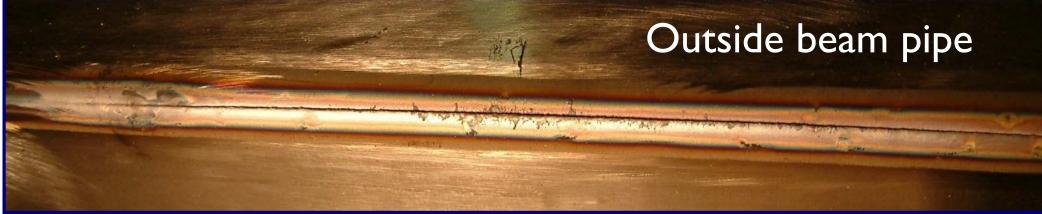

What is needed to intercept particles at large transverse amplitude or with the wrong energy to avoid quenching a magnet?

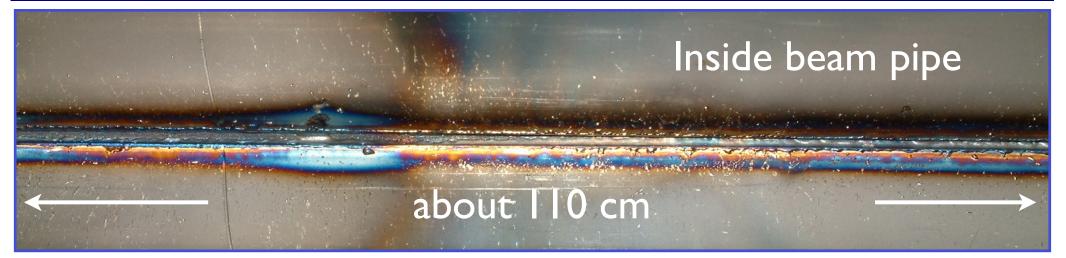

3 years ago something went wrong during a test ...

LHC extraction from the SPS 450 GeV/c, 288 bunches
Transverse beam size 0.7 mm (1 σ)
1.15 x 10¹¹ p+ per bunch, for total intensity of 3.3 x 10¹³ p+
Total beam energy is 2.4 MJ, lost in extraction test (LHC 334 MJ)

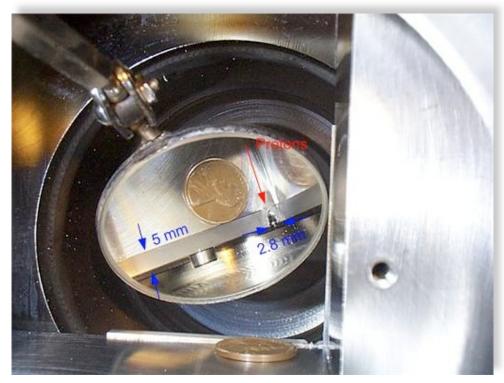

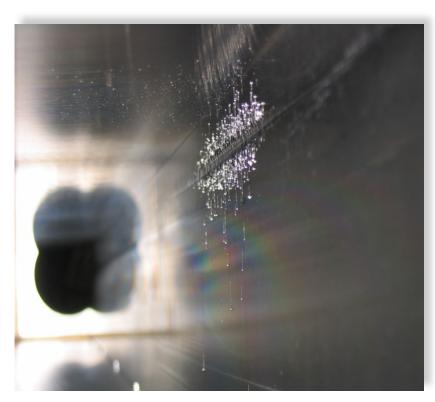

Tevatron accident in 2003 (courtesy of N. Mokhov)

Accident caused by uncontrolled movement of beam detectors (Roman Pots) which caused a secondary particle shower magnet quench → no beam dump → damage on approximatively 550 turns

Tungsten collimator. Tmelting = 3400 °C I.5 m long stainless steel collimator

Experiment simulating beam-losses

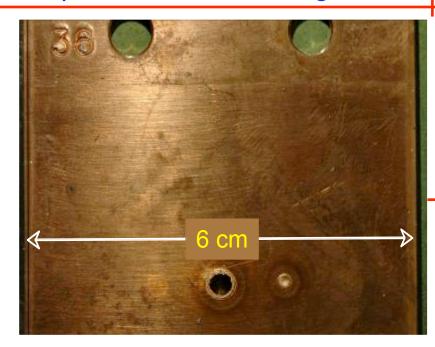

Controlled SPS experiment

 $8*10^{12}$ protons \Rightarrow 0.1% full LHC power

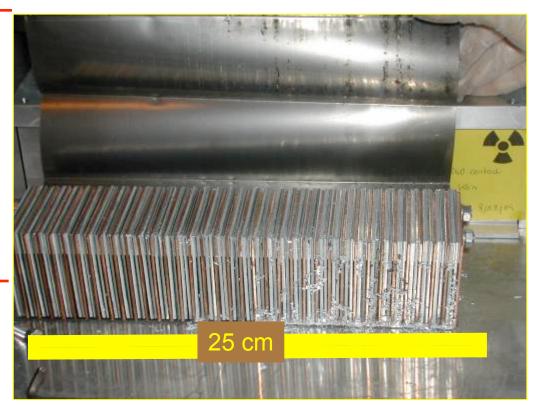

Clear damage

Beam size $\sigma x/y = 1.1 \text{ mm}/0.6 \text{ mm}$

 $2*10^{12}$ protons \Rightarrow below damage limit

From V. Kain

0.1 % of the full LHC beams

Aim of the experiment:

- I. test on different material the possible damage cause by beam-loss
- 2. test the codes used for predict possible damages in the real machine

Collimation system for machine protection

Two sections in LHC dedicated to beam cleaning:

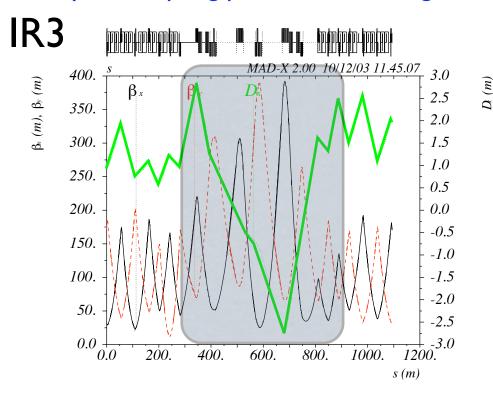

IR3 momentum cleaning \rightarrow remove particles with too large dp/p (> $\pm 10^{-3}$) thanks to large dispersion.

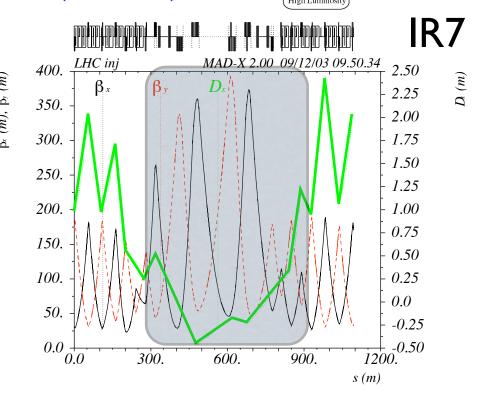

$$\Delta x = D \frac{\Delta p}{p}$$

IR7 <u>betatron cleaning</u> → remove particles at too large amplitude. Dispersion as small as possible.

$$x_{MAX} = \sqrt{\epsilon \beta}$$

CERN	LHC	2801	8.33	7.000
CERN	LEP	2801	0.12	0.100

The length of the LHC dipoles (15 m) has been determined: by the best design for the tunnel geometry and installation and by the maximal dimensions of (regular) trucks allowed on European roads.

Temperature margin and quenches....

Lower temperature margin near the beam!

Limiting beam losses: 10^8 p/m at small grazing angle for a total circulating intensity of 3.3 10^{14} p

Other possible sources of quenches:

- I. **mechanical friction**, for example during current ramp, between the conductors. Few µm are enough. Magnets are "trained" before installation and they keep memory of the training at least since the next quench.
- 2. **failure of the cooling system.** Depending on the case of failure, magnets can heat up slowly or not...

but every dipole stores about 7 MJ at collision the stored energy is about 350 MJ per beam

So, one need:

- I. to exclude the magnet from the ARC powering, since all the magnets are IN SERIES per ARC.
- 2. to discharge fast the power of the quenching magnet octant (time constant about 100 s), and dispersing by heating up the magnet the power that otherwise will accumulate near the quenching zone.
- 3. to extract the beam as fast as possible, meaning within one turn from the quench detection, before risking to damage mechanically the machine with the beam.

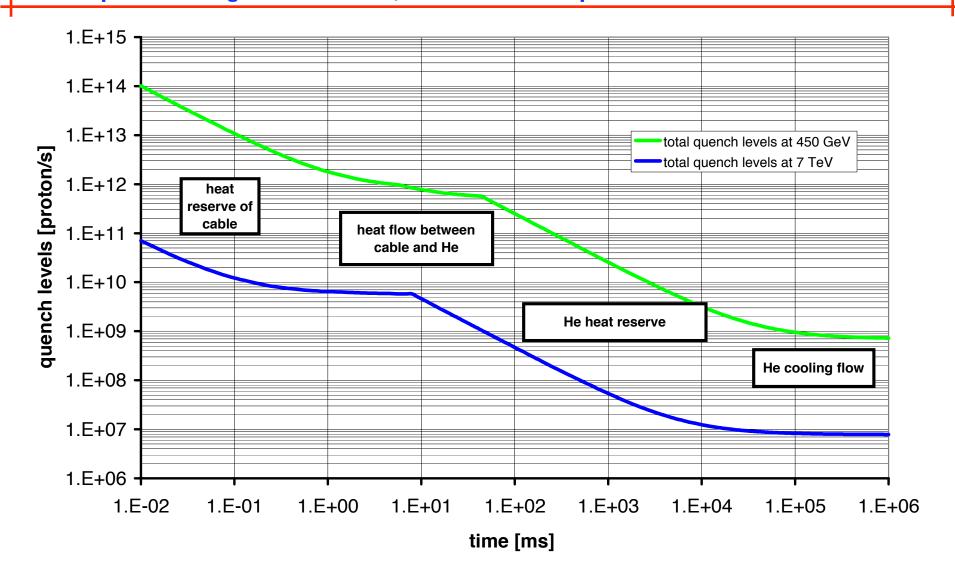

The different time scale of the two processes helps:

I beam turn every $\sim 90~\mu s$ while a quench develops on at least few ms. However, quench detection, power extraction and beam extraction has to be fast and reliable.

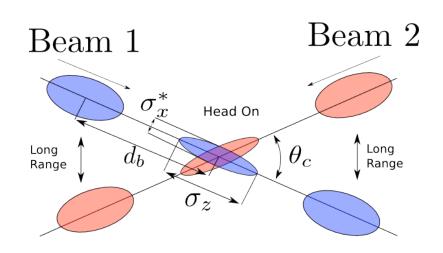

Quench levels are varying with energy

In a synchrotron, the magnetic field increases with energy to keep particles on the circular trajectory. This means that both the current as the field are larger at 7 TeV than at 450 GeV.

The Temperature margin is the reduced, one can loose less particles....

Beam-Beam interaction

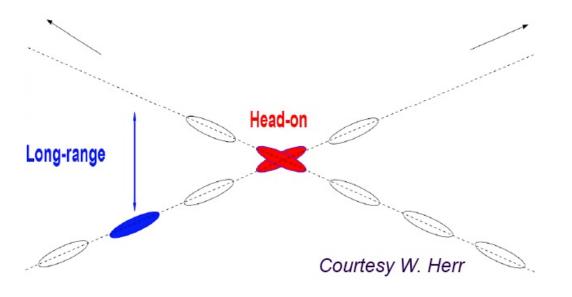

The two beams travels one near the other at the IP

The electromagnetic field generated by one beam is felt by other ⇒ Beam-Beam

Three classes of beam-beam effects:

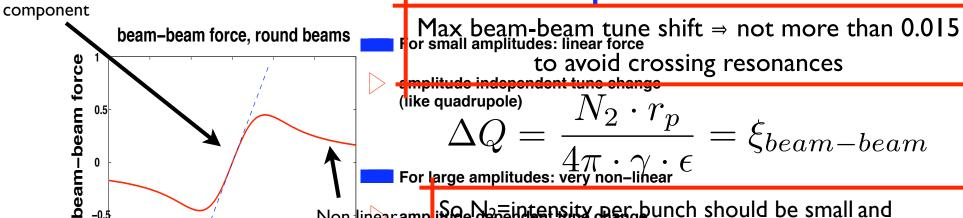

- A)Long range
- B) Packman bunches
- C) Head-on

Packman bunches are the bunches of one beam that at the IP don't see a correspondant bunch of the other beam.

As a results, for them the tune, orbit and chromaticity will be different from the other bunches

Beam beam tune spread

For large amplitudes: very non-linear

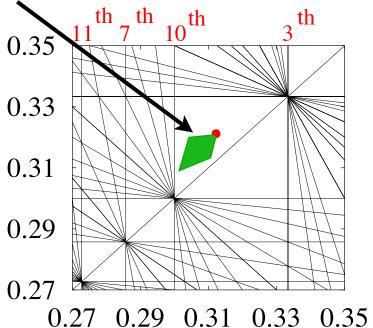

dependence

Non linear amp is the dependent sity dhange bunch should be small and Amplitude-for(tike remainstated) should be big, exactly the opposite to have large Luminosity. An optimum has to be chosen

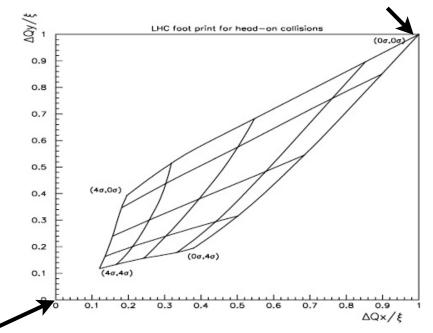

Quadrupole-like

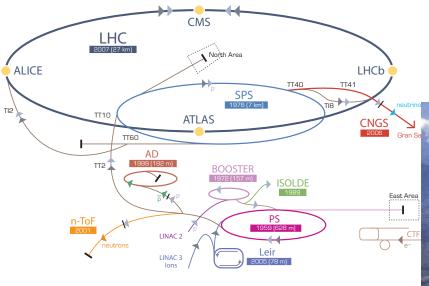

Max beam-beam

No beam-beam

Electron clouds

Electron cloud in the vacuum beam pipe can be created by "avalanche" process:

- 1. few primary e⁻ generated by as photoelectrons, from residual gas ionization, extract by Synchrotron radiation
- 2. p+ bunches accelerate e⁻ (this depends from the bunch separation, i.e. 25 nsec in the LHC)
- 3. e impact on the wall and extract secondary e

and so on ... and the cloud can generate:

- a) heating of the beam pipe ⇒ magnet heating
- b) beam instabilities

Courtesy F.Ruggiero)

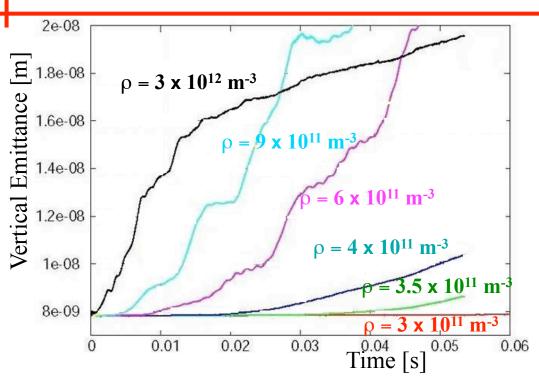

Animation from O. Brüning simulation

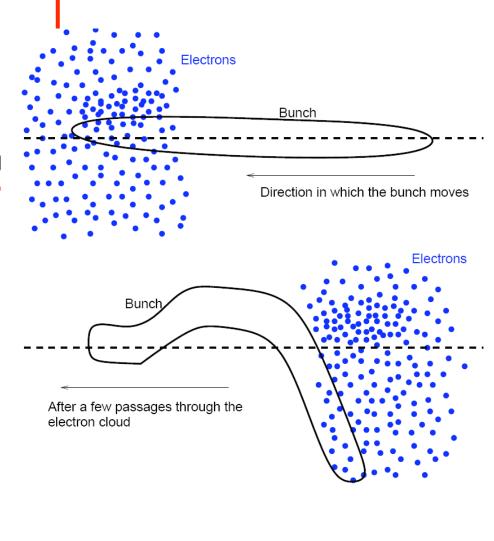

→ 10 subsequent bunch passages

Color describes the formation of the electron cloud

Electron clouds issues on beam

- . Bunch passage, electrons accumulated near beam centroid
- 2. If there is offset between and tail:
 - → tail feels transverse electric field created by head
 - → tail become unstable
- 3. Particles mix longitudinally
 - → also head can become unstable (above threshold)
