

Some personal memories of the PS and LEP.

Creation of the PS.

The “strong-focusing” or “alternate gradient” synchrotron was invented by Courant, Livingston and Snyder (3 outstanding physicists) in 1963. Christophilos had invented it some months before, but never published this.

At the time, CERN had the fortune to have an outstanding accelerator team, including John Adams, Marvin Hine, and Simon Vander Meer. The PS was a great achievement.

(Not to remember, in 1960, one of the first PS experiments: my own attempts, together with Roberto Salmeron, to see neutrino events in the Ramm 1m diameter bubble chamber. We didn't see any.)

where $N_{E'}$ is now a counting rate per constant energy (or range) difference.

One can also calculate the total number of electrons of energy E' which escape as a check of the above result. If this is again done for a volume with a square centimeter base at the surface, the total number of electrons of energy E' which escape from a volume element $d\tau$ at x is

$$\int_0^{2\pi} \int_0^{\infty x^{-1/2} R' N_{E'}} \frac{d\tau}{4\pi} \sin \theta d\phi d\theta dx = \frac{N_{E'}}{2} \left[1 - \frac{x}{R'} \right] dx.$$

Integration over x from 0 to R' gives $N_{E'} = 4R'$.

If we integrate $N_{E'}$ over R'' from 0 to R' we get

$$\int_0^{R'} \frac{N_{E'}}{4} dR'' = \frac{N_{E'}}{4} R',$$

as we should, since the total count due to degraded pulses should equal the total number of electrons escaping.

The above result states that electrons of energy E' which escape from the crystal are degraded with equal probability into all energies below E' , since the above results are independent of E' or E'' . The fraction of electrons of energy E' which escape from the crystal is equal to $\frac{1}{4}$ the fraction of the volume of the crystal which lies in a surface layer of depth R' . These two facts can be used in a graphical method to correct distorted beta-spectra for the effect due to the escape of electrons.

A similar analysis can be made for the escape of photons from a crystal, substituting an exponential absorption for the range. The solution in this case involves the F -function, which is somewhat awkward, but one can consult tables of this function to obtain numerical answers.

The Strong-Focusing Synchrotron—A New High Energy Accelerator*

ERNEST D. COURANT, M. STANLEY LIVINGSTON,† AND HARTLAND S. SNYDER
Brookhaven National Laboratory, Upton, New York

(Received August 21, 1952)

Strong focusing forces result from the alternation of large positive and negative n -values in successive sectors of the magnetic guide field in a synchrotron. This sequence of alternately converging and diverging magnetic lenses of equal strength is itself converging, and leads to significant reductions in oscillation amplitude, both for radial and axial displacements. The mechanism of phase-stable still synchronous oscillations applies, with a large reduction in the amplitude of the associated radial synchronous oscillations. To illustrate, a design is proposed for a 30-Bev proton accelerator with an orbit radius of 300 ft, and with a small magnet having an aperture of 1×2 inches. To illustrate, on nearly all design parameters are less critical than for the equivalent uniform n machine. A generalization of this focusing principle leads to small, efficient focusing magnets for ion and electron beams. Relations for the focal length of a double-focusing magnet are presented, from which the design parameters for such linear systems can be determined.

BETATRON OSCILLATIONS

RESTORING forces due to radially-decreasing magnetic fields lead to stable "betatron" and "syn-

* Work done under the auspices of the AEC.

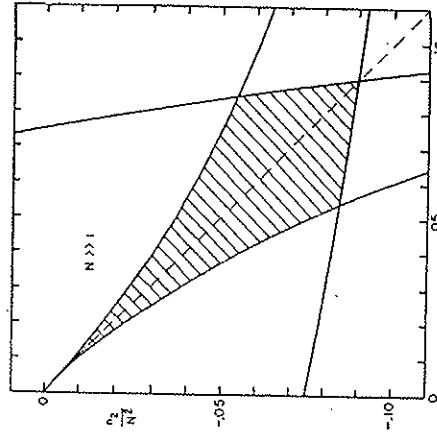

FIG. 2. Region of stability for radial and vertical oscillations for a large number of sectors N , in terms of the parameters n_1/N and n_2/N^2 .

corresponding amplitudes are inversely proportional to these oscillation frequencies, for a given angular deviation. Therefore, the aperture required to accommodate either mode can only be reduced at the expense of the other mode, and the minimum aperture both occurs with $n=0.5$.

The focusing forces can be greatly strengthened by letting α vary in azimuth. Suppose the circular orbit to consist of N sectors of equal length with n_1 and n_2 in alternate sectors. The equations of vertical and radial oscillations are then

$$\frac{d^2r}{dt^2} + n_1^2 r = 0; \quad \frac{d^2\theta}{dt^2} + (1 - n_2)r = 0; \quad (2a)$$

$$\frac{d^2r}{dt^2} + n_2^2 r = 0; \quad \frac{d^2\theta}{dt^2} + (1 - n_1)r = 0; \quad (2b)$$

The effective frequency of the "betatron" oscillations is given by:

$$f_r = f_r = (\mu N/2)f_0 \quad (\text{for large } N), \quad (6)$$

which can be compared with the frequencies given in Eq. (1) for constant n . Therefore, the amplitudes of oscillation and the aperture requirements can be made much smaller by the use of a large number of sectors N and correspondingly large positive and negative values of n in successive sectors. As a numerical example, consider a synchrotron of 240 alternating sectors, with $n_1 = 3600$ and $n_2 = -3600$. The radial aperture requirement is about $1/24$ that for the corresponding synchrotron with a constant n of 0.6, and $1/20$ for the vertical aperture. Ion trajectories are not sinusoidal as in the standard synchrotron, but are composed of sections of alternately harmonic and hyperbolic functions. Figure 3 is a schematic illustration of two typical oscillating orbits committed for the case discussed in 4.6.

$K_S - K_L$ interference.

After CP violation was discovered in 1964, by Christenson, Cronin, Fitch and Turley, I had the idea that one way to learn more about CP violation was by studying the interference of K_S and K_L in the $\pi^+ - \pi^-$ decay. End of '64 I came to CERN on sabbatical, for half a year, to do this. It turned out to be a longer job, and so I stayed an extra year.

Gargamelle, neutral currents, quarks.

In 1973 the weak neutral current was discovered at the PS, using the Gargamelle bubble chamber. This discovery established the E-W unified gauge theory, an enormous event in the history of particle physics.

In 1974 the Gargamelle team, comparing deep inelastic neutrino scattering with SLAC results of electron scattering, gave the first clear evidence for the charges and therefore the quark nature of the "partons".

1970-'72 Development of "renormalizable",
consistent, gauge theory which:
• unifies electromagnetic and weak interaction;
• predicts "neutral current" weak interaction;
• predicts heavy vector particles W^+ , W^- , Z^0

Events induced by neutral particles and producing hadrons, but no muon or electron, have been observed in the CERN neutrino experiment. These events behave as expected if they arise from neutral current induced processes. The rates relative to the corresponding charged current processes are evaluated.

We have searched for the neutral current (NC) and charged current (CC) reactions:

$$\text{NC } \nu_\mu / \bar{\nu}_\mu + N \rightarrow \nu_\mu / \bar{\nu}_\mu + \text{hadrons}, \quad (1)$$

$$\text{CC } \nu_\mu / \bar{\nu}_\mu + N \rightarrow \mu^- / \mu^+ + \text{hadrons} \quad (2)$$

which are distinguished respectively by the absence of any possible muon, or the presence of one, and only one, possible muon. A small contamination of $\nu_e / \bar{\nu}_e$ exists in the $\nu_\mu / \bar{\nu}_\mu$ beams giving some CC events which are easily recognised by the $e^- e^+$ signature. The analysis is based on 83 000 ν pictures and 207 000 $\bar{\nu}$ pictures taken at CERN in the Gargamelle bubble chamber filled with freon of density $1.5 \times 10^3 \text{ kg/m}^3$. The dimensions of this chamber are such that most

Multiwire proportional (Charpak) chambers.

1968 Charpak invents the MWP chamber.

1969 A group of us decide to try to use this technology to achieve more precise measurements of CP violation parameters. The design of large, experimentally useful MWP chambers turned out to be a substantial challenge. Successful design was achieved in 1970, permitting very much improved understanding of CP violation in K decay.

Result:
in interval
 $(6 - 21) \text{ GeV}/c$
 $\sigma(\Lambda p) = 34.6 \pm 4 \text{ mb}$
 $\sigma(\Lambda n) = 34.0 \pm 8 \text{ mb}$

Fig. 3. (a) and (b) The measured total cross-sections $\sigma(\Lambda p)$ and $\sigma(\Lambda n)$ as a function of momentum. Only statistical errors are shown. The prediction from quark-model additivity sum rules is indicated by the broken lines. The range between the lines covers the uncertainty of the data used in evaluating the sum.

Conclusion: the PS permitted good progress
in particle physics.

LEP, the “ultimate” e⁺ - e⁻ storage ring collider.

To my knowledge, first suggestion for the “ultimate e+ - e- collider came from Burt Richter, in the 70's.

N. B.: As best I know, Tini Veltman, was responsible for the suggestion, in the late 70's, and which was accepted, that the tunnel should be constructed so as to permit a future p – p collider, now the LHC.

The beginning of the ALEPH collaboration was summer of '80. Maybe a dozen of us, including some members of the CDHS neutrino experiment, Jaques Lefrancois, and Rene Turley. We agreed that we would like to focus on a special purpose detector, but soon agreed that we could not think of an interesting “special purpose”, and so focused on a general purpose detector.

My own first concept, given the expected isotropy of the Z decay, was not brilliant: a spherical magnet. This was not adopted.

The most important insight, in my opinion, the one which dominated the ALEPH design, came from Jaques Lefrancois: the electro-magnetic calorimeter should focus on angular, rather than energy, resolution.

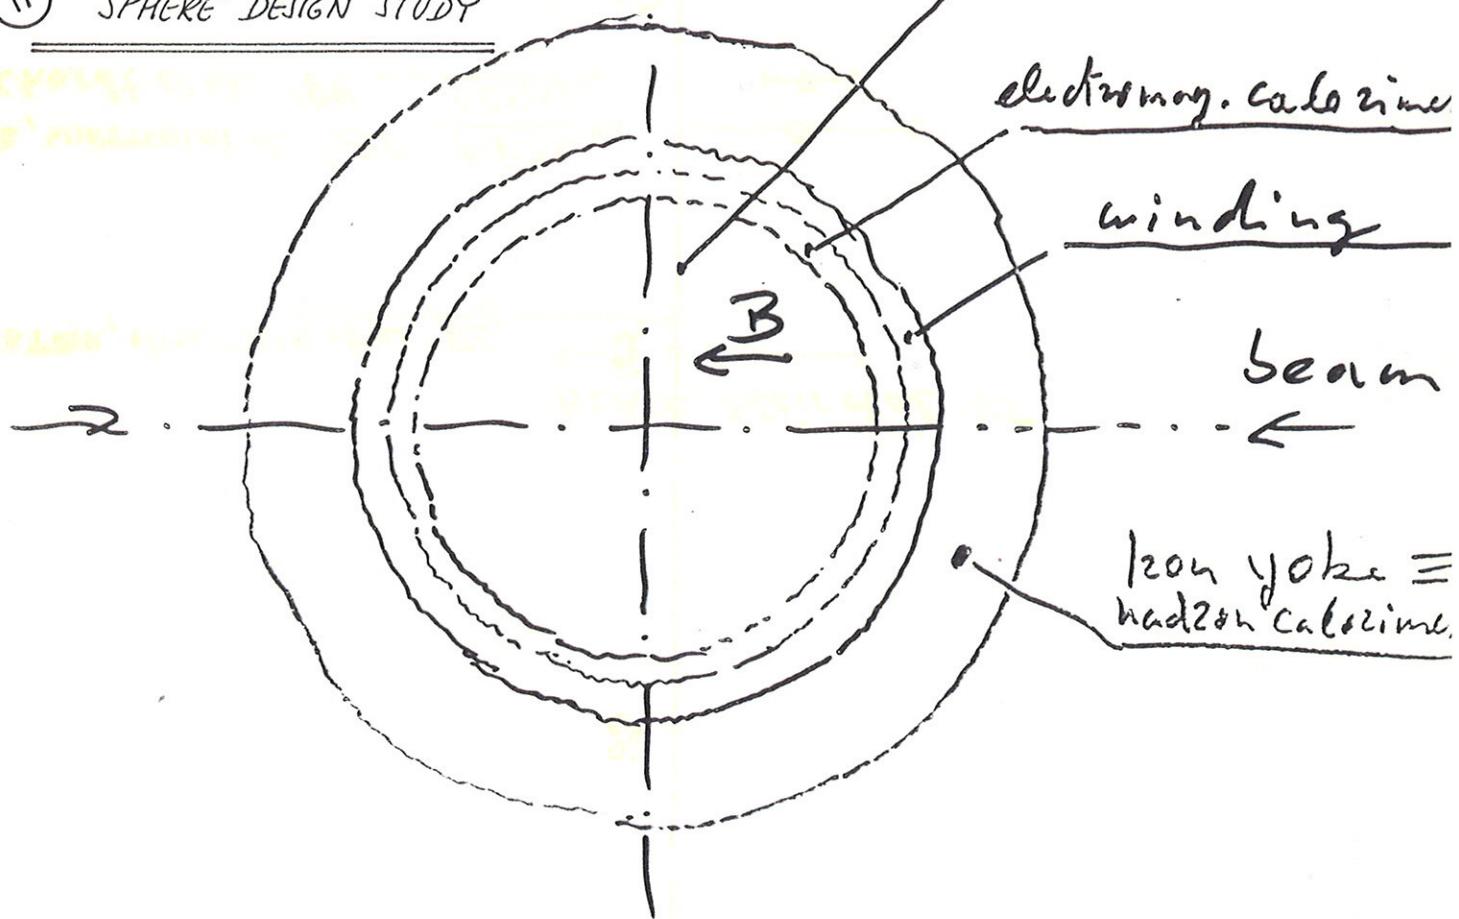

ALEPH construction: we were managed beautifully by the Technical Coordinator, Pierre Lazeyras.

$\vec{E} \times \vec{B}$ EFFECT IN ALEPH TPC

The aim of this report is to study the $\vec{E} \times \vec{B}$ effect measured in the TRIUMF TPC and make some quantitative estimates for the worsening of the $R\phi$ resolution of our TPC because of this effect.

SOME DATA ON TRIUMF TPC

Effective dimension of the cell 6 mm

Gas 80% A + 20% CH₄,

$\vec{E} \times \vec{B}$ angle, at $B = 8.5$ Kg, $\psi = 32^\circ$ ($\tan 32^\circ = 0.624$)

Resolution for 0° track .450 mm

Resolution for 32° track .180 mm

Resolution $\vec{E} \times \vec{B}$ at $0^\circ = \sqrt{\sigma^2(0^\circ) - \sigma^2(32^\circ)} = .412$ mm

the shape of the cell is shown in Fig. 2.

From Sauli report [1] at 80% A + 20% CH₄, we have

Primary ionization $N_e = 2.67$ pair/mm

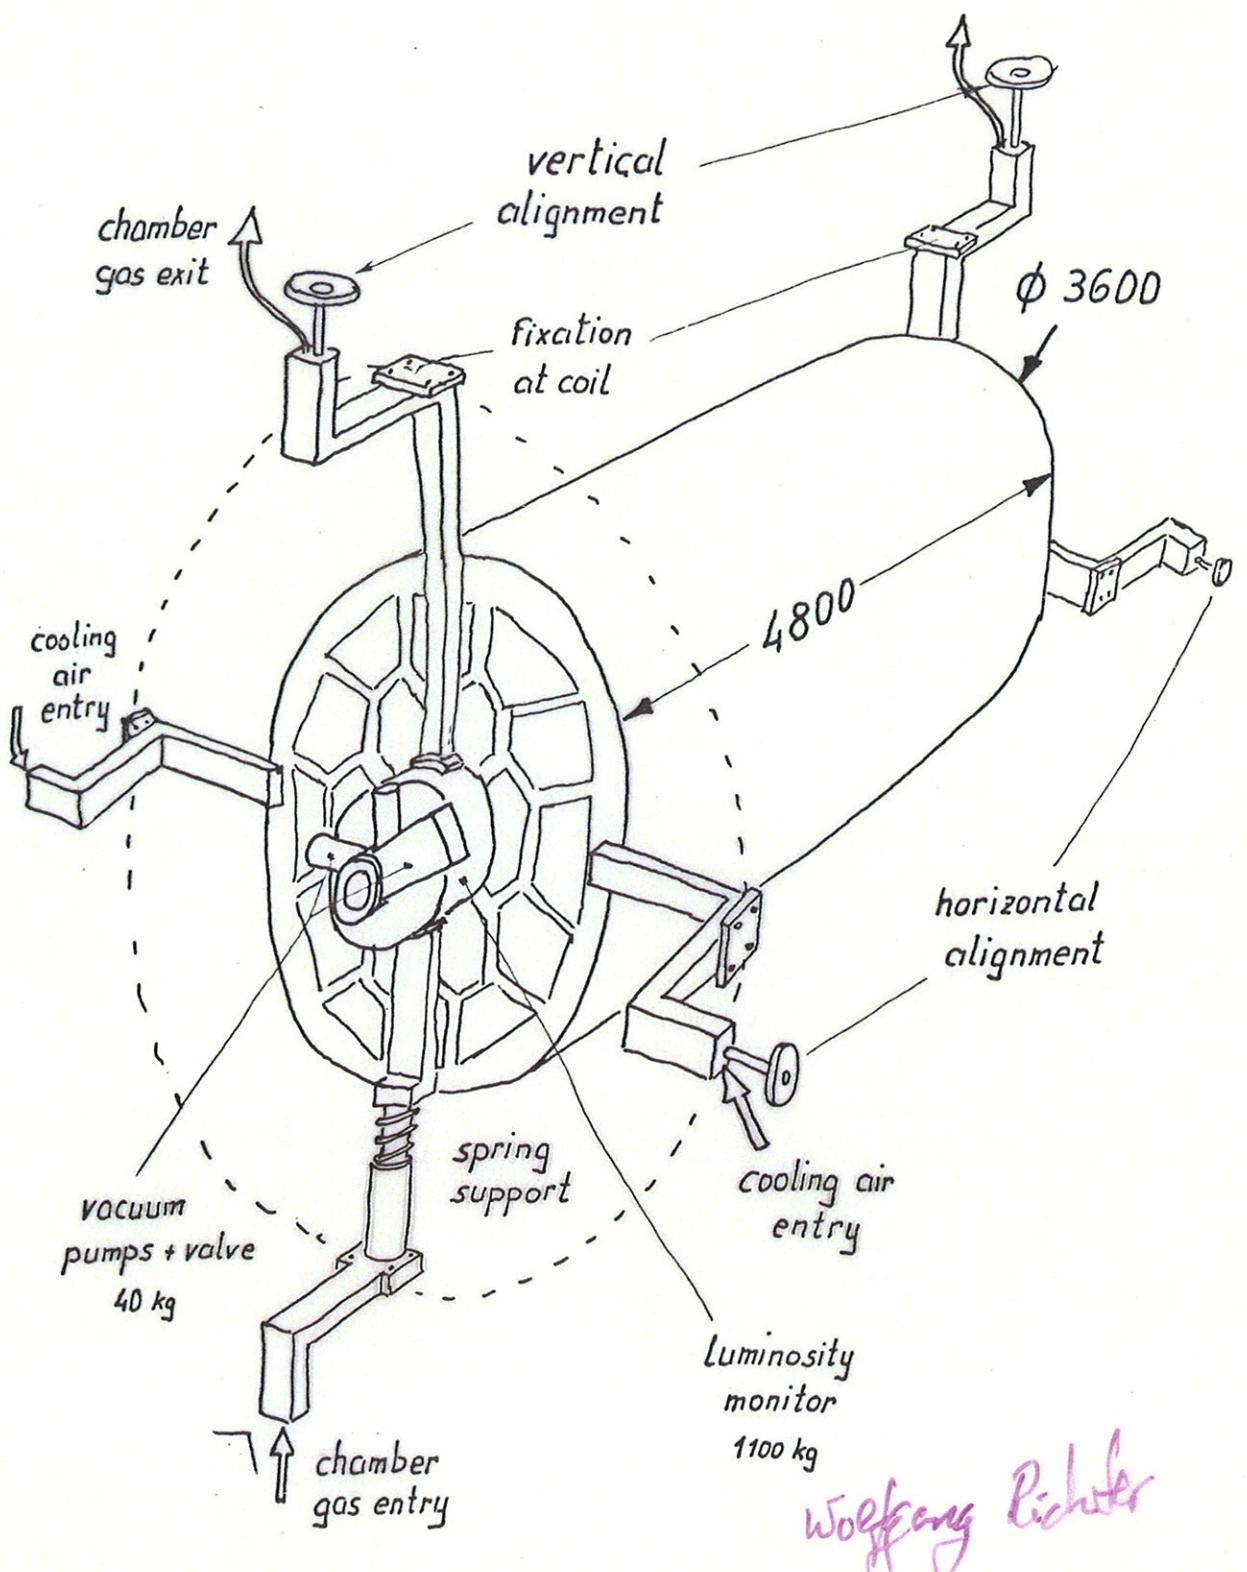

Total " $N_{Tot} = 8.58$ pair/mm
