

# The transverse size of the nucleon

Laurent Schoeffel (CEA)

4th march 2010

# Plan

- description of models describing the transverse size of the nucleon (others than GPD models)
- status of experimental knowledge of today on transverse nucleon size
- expected impact of planned COMPASS measurements in this field (show projections for  $t$ -slope measurements)

# Processes under study

Exclusive production of Vector Mesons or real photon (DVCS)

First part: at small  $x$  values  $x < 0.01$

Second part: dedicated measurement for DVCS at COMPASS ( $x \sim 0.1$ )  
with large statistics

$t$  is the momentum exchange (squared) at the proton vertex

# Nucleon structure from the Basic principle

The Fourier transform of the square root of the cross section (VM) is directly related to the S matrix

$$S(x, r_Q, b) = 1 - \frac{1}{2\pi^{3/2} N(Q)} \int d^2 \Delta e^{-i\Delta b} \sqrt{\frac{d\sigma}{dt}}$$

$b$  ( $:=b_{\perp}$ ) is the impact parameter in the proton

$N(Q)$  is a flux factor (coming from the overlap of  $\gamma^*$  and VM wave function)

**S tells us how dense the nucleon looks like!**

$S=0$  means blackness (unitarity limit)

and  $1-S^2$  is the interaction probability of the  $\gamma^*$  (or dipole) that hits the nucleon at impact parameter  $b$

Program: Measure  $d\sigma/dt$ , extract  $S$  and then conclude on the proton structure

# Result from $\rho$ meson from HERA[ $Q^2$ ]

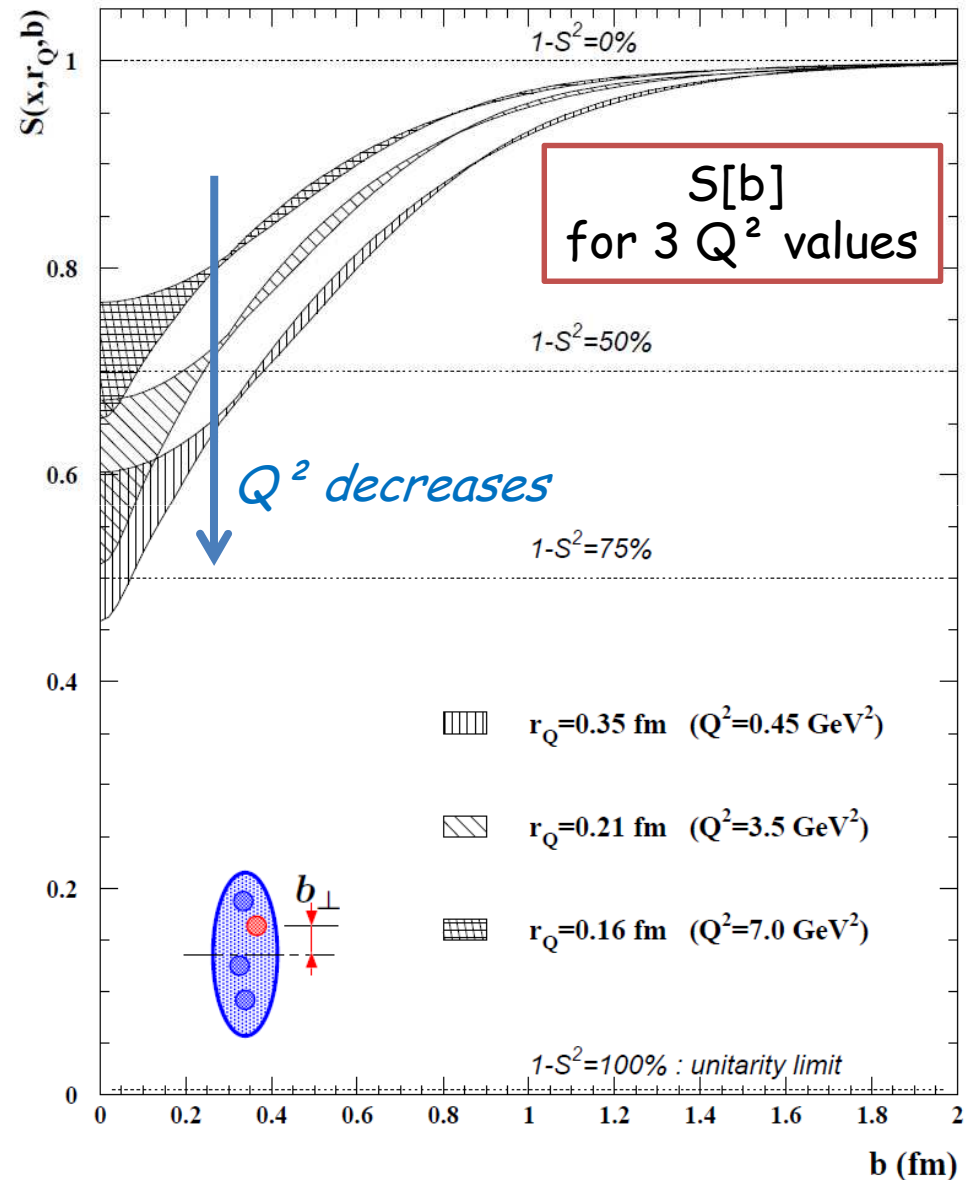

From Munier et al. + H1 exp.  
 note: analysis done for  $x < 10^{-2}$   
 with HERA data on  $\rho$  exclusive  
 production

Large error at small  $b$  due to the  
 lack of data for  $|t| > 0.6 \text{ GeV}^2$

Interaction probability  $> 50\%$  ( $75\%$ )  
 in the center of the proton  
 $b < 0.3 \text{ fm}$  (« black disk »)

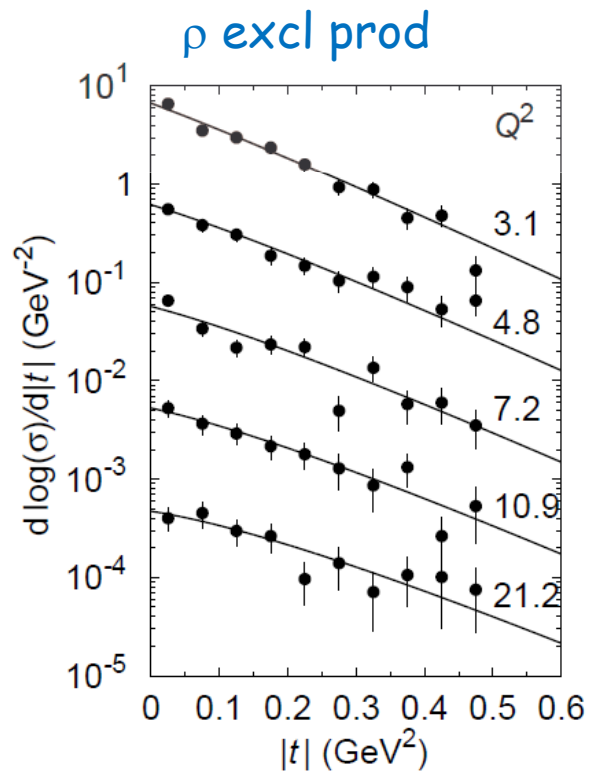

And then, proton is more transparent  
 when  $b$  is increasing ('grey area')  
 (more transparent also at larger  $Q^2$   
 -smaller dipole (probe) size-  
 similar to optics)

Similar results for  $J/\psi$

# t-dependence measurements at HERA

Measurements done for all processes and various  $Q^2$   
The x range for these measurements is between  $10^{-4}$  and  $10^{-2}$   
*We note also the good agreement with theory (dipole model)*

# Compilation of t-slopes measurements from H1/ZEUS

From previous measurements we can parameterise the cross section as  $d\sigma/dt \sim \exp(Bt)$  and then extract B values (t-slopes)

# Interpretation of the t-slopes

At large  $Q^2 > 8 \text{ GeV}^2$   
 all measurements scale  
 with  $Q^2$  ( $B \sim 5 \text{ GeV}^{-2}$ )  
 Here the proton is probed  
 with a point-like configuration  
 $\Rightarrow$  It corresponds to the  
 proton size

At small  $Q^2$ : we observe the  
 effect of the VM size in  
 $r^2 \sim 1/(Q^2 + M^2)$

Then we can write the measured t-slope  $B$  as the sum of both contributions

$$B = B_p + B_{VM}$$

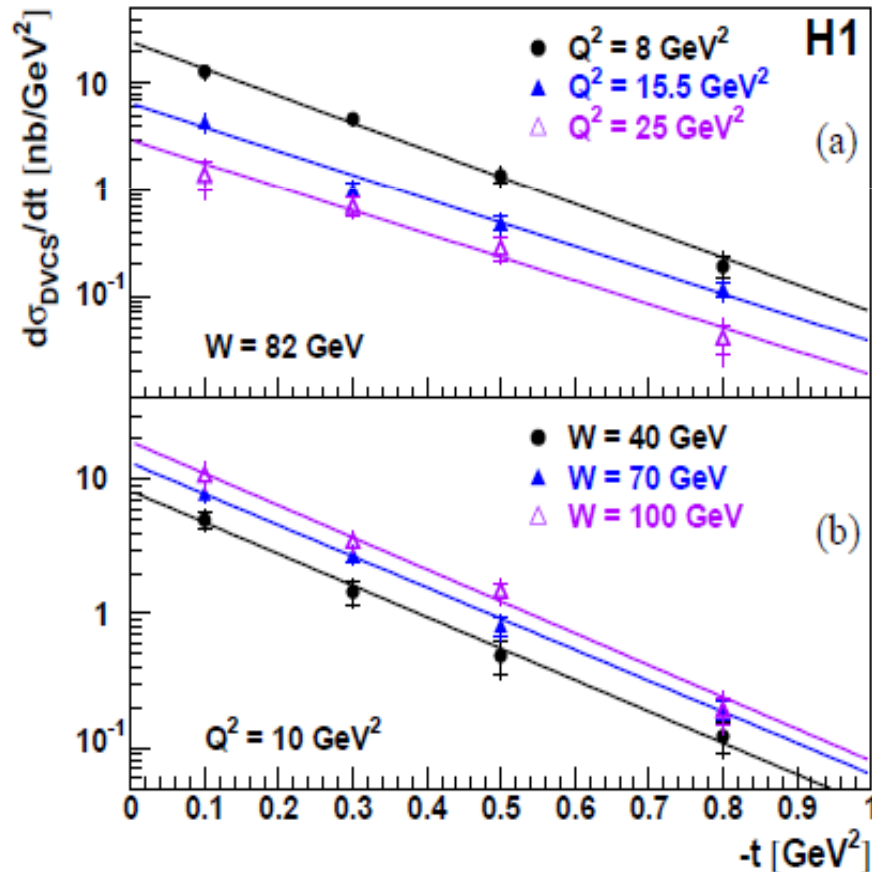

$B_p$  corresponds to an average transverse proton-size (in 2D) of 0.6fm

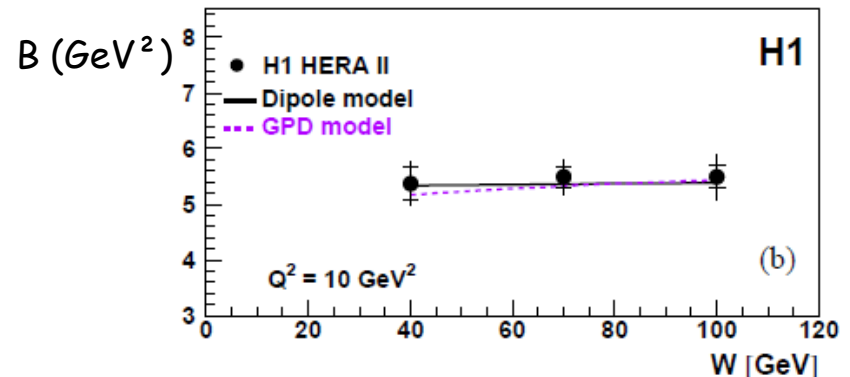

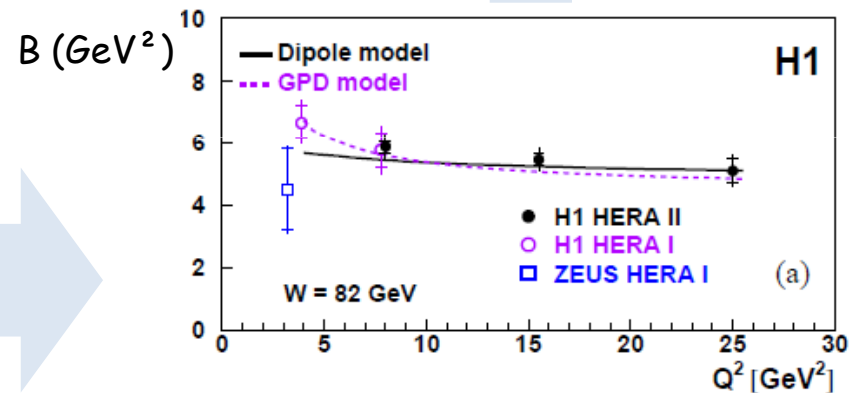

# Let's focus on DVCS measurements

Interesting process as we do not have the complexity of VM wave function in the interpretation

In the following  $W^2 \sim Q^2/x$

In average  $Q^2 > 5 \text{ GeV}^2$   
 $b = 5.41 \pm 0.14 \pm 0.31 \text{ GeV}^{-2}$   
 which gives  $\Rightarrow$   
 $[\langle r_T^2 \rangle]^{1/2} = 0.64 \pm 0.02 \text{ fm}$

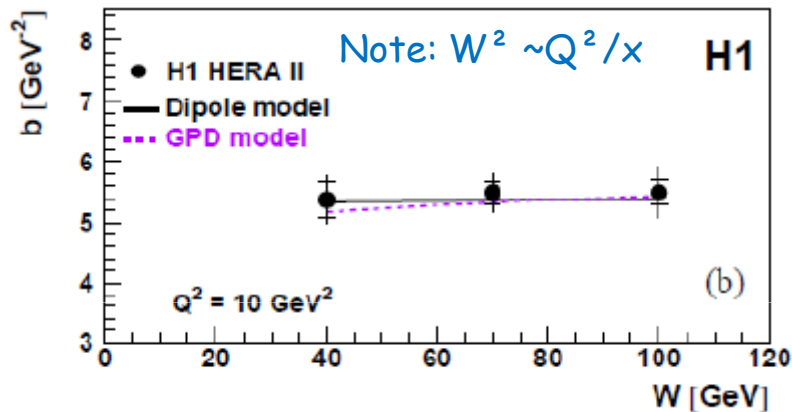

# The interplay between $x$ and $t$

We can examine the dependence of  $B(x)$

Let's write  $B(x) = B_0 + \alpha' \text{Log}(1/x)$

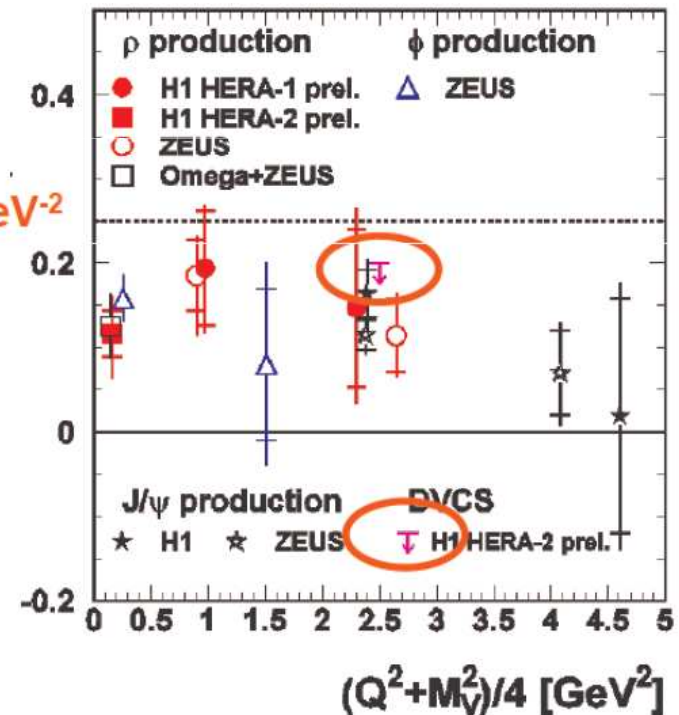

From previous slide, we know that  $\alpha'$  is small

$\alpha' < 0.25 \text{ GeV}^{-2}$

For all VM + DVCS at HERA we observe a small value of  $\alpha'$  and even smaller values when  $Q^2$  is increased

Then, *negligible* interplay between  $x/t$  at small  $x$  ( $x < 0.01$ ) [within errors]

# Discussion

As  $B(x) = B_0 + \alpha' \text{Log}(1/x)$  Then  $[\langle r_T^2 \rangle]^{1/2} \sim \alpha' \text{Log}(1/x)$

$\alpha'$  reflects the spread of partons in the transverse dimension as a function of the rapidity ( $\text{log}(1/x)$ ). It makes the link between the  $x$ -dynamics and the transverse structure of the nucleon

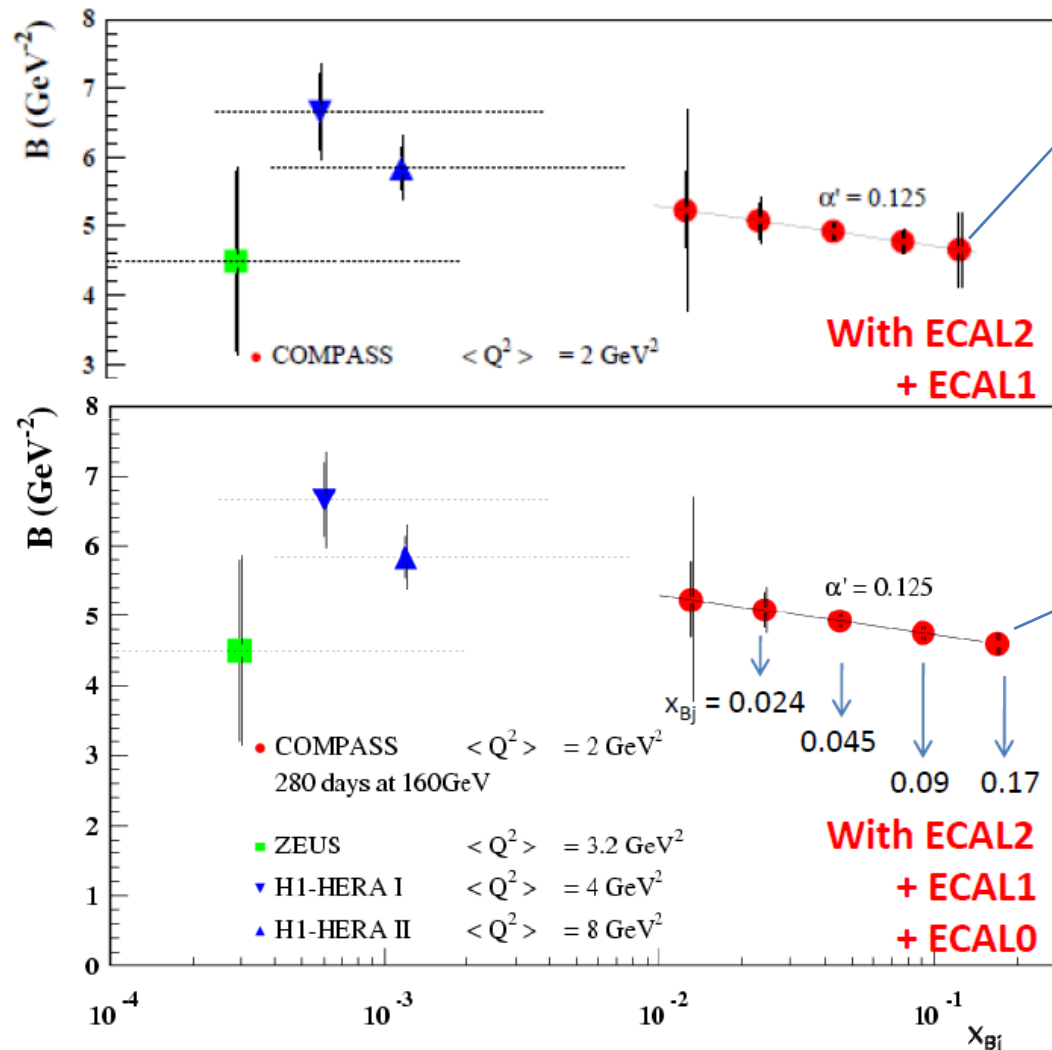

$\alpha'$  is found small at small  $x$  (compatible with a hard process)

We do not know the value at larger  $x$  ( $x \sim 0.1$ ) in the domain  
Where COMPASS can provide measurements with high precision

*This is a fundamental issue encoded in GPDs whose evolution in  $Q^2$   
and rapidity must be predicted!*

# t-slopes projections for COMPASS

With 3% error on the BH subtraction

146 DVCS evts

2 years of data  
 160 GeV muon beam  
 2.5m LH<sub>2</sub> target  
 $\epsilon_{\text{global}} = 10\%$ ,  
 Lumi=1222 pb<sup>-1</sup>

1127 DVCS evts

With the present projection  
 we can determine:

$B$  with an uncertainty  $< 0.1 \text{ GeV}^{-2}$   
 $\alpha'$  with an error better than  $3\sigma$   
 if  $\alpha' > 0.30 \text{ GeV}^{-2}$  with ECAL1+2  
 if  $\alpha' > 0.16 \text{ GeV}^{-2}$  with ECALO+1+2

# Discussion

(1)

the correlation between  $x/t$  variables is also encoded in the BC(S)A prediction

- a. From  $t$ -slope measurements, determine  $B(x) \Rightarrow B_0$  and  $\alpha'$
- b. To be included into the BC(S)A calculations
- c. Check what comes out w.r.t. direct BC(S)A data (see other talks)

(2)

Orbital angular momentum: comes with GPD Eq

We know the upper limit:  $|Eq| < q(x)m ||r_{\perp}||[x]$

Where  $||r_{\perp}||[x]$  can be determined directly from  $t$ -slopes  $B(x)$

Then, most probably main contribution to  $Lq$  comes from not too large  $x$  and with direct determinations of  $b(x)$  or  $||r_{\perp}||[x]$  at various  $x$ , we can derive the upper limit on  $Lq$

# Summary

With HERA data on VM and DVCS at small  $x$  ( $x < 0.01$ ) we have a clear view of the transverse nucleon size in this kinematic domain

Also with the conclusion that we observe a *negligible* interplay between  $x$  and  $t$

Example:  $\alpha' < 0.2 \text{ GeV}^{-2}$  with 90% confidence level for DVCS

As we have seen, DVCS is the best process for these studies as it does not suffer from the lack of knowledge of the VM wave function in the interpretation

COMPASS experiment is dedicated to produce high statistics DVCS cross section measurements and then extract  $t$ -slopes with high precision as well as the interplay between  $x$  and  $t$

It can give a definite answer on the transverse size of the nucleon for  $0.01 < x < 0.1$  and moderate  $Q^2$
