# LHC results on electroweak and Higgs physics

---

**corrinne mills (UIC+FNAL)**

CTEQ @ PITT

24+25 July 2019

# Introduction

---

- Electroweak physics has been a cornerstone of collider physics since discovery of W and Z bosons in the early 80s
  - *Higgs boson is an inextricable part of this*
- The last time I lectured at this school (2011), the Higgs boson had yet to be observed
- As the dataset has increased, focus on increased precision and search for increasingly rare processes
- Rather than trying to cover exhaustively the dynamic landscape of all measurements, focus on key examples
- Also talk about detector performance: results chosen to illustrate concepts, don't necessarily represent the state-of-the-art performance
- My career at hadron colliders: CDF (Tevatron), ATLAS, now CMS
  - *I am also excited to talk about silicon detectors at the discussion sections*
- Mistakes, opinions, and biases are all my own

# The Large Hadron Collider, CERN

Lac Lemman

The Alps

Genève

airplanes go here

CERN

world's highest-energy  
particle collider  
pp collisions at  
 $\sqrt{s} = 7 \rightarrow 8 \rightarrow 13$  TeV

# Colliding protons

- High energies  $\leftrightarrow$  small distance scales at the LHC
- Proton is not a point particle: quarks, gluons, even antiquarks
  - $\rightarrow$  Most collision events **gluon-gluon**
- Don't know momentum carried by individual partons ( $p_z$ )
  - $\rightarrow$  use transverse momentum ( $p_T$ )

# Rapidity and pseudorapidity (“ $\eta$ ”)

**Rapidity  $y$  is a Lorentz-invariant way to express the polar angle of a particle**

CTEQ2011 Schellman

$$y \equiv \frac{1}{2} \left( \frac{E+p_{\parallel}}{E-p_{\parallel}} \right)$$
$$E = \frac{1}{2} e^y \sqrt{m^2 + p_T^2}$$

Lorentz Invariant Phase Space can be written as

$$\frac{d^3p}{2E} = d\phi \, d\cos\theta \, p^2 dp = d\phi dy dp_T^2 = 2\pi dy dp_T^2$$

In frame where  $p_z = 0$ ,

$$\delta y \approx \delta\theta + \mathcal{O}(\delta\theta)^3$$

equivalent to small variations in the polar angle  $\theta$ .

**For massless particles, the rapidity reduces to the pseudorapidity**

$$\eta = -\ln(\tan \theta/2)$$

# Hadron Collider Kinematics

$$\vec{p}_T = (p_x, p_y) \quad p_T = p \sin \theta, \quad E_T = E \sin \theta$$

# Collider physics units

- **Energy measured in eV**

→ *Energy acquired by electron accelerated through 1 Volt*

→ **1 GeV** =  $10^9$  eV =  $1.6 \times 10^{-10}$  Joules

- The rest follows from the famous equation

$$E^2 = p^2 c^2 + m^2 c^4$$

→ *Momentum in **GeV/c***

→ *Mass in **GeV/c<sup>2</sup>***

→ *Typically set **c = 1***

- **Then work with four-vectors:**

$$p = (E, -p_x, -p_y, -p_z)$$

- **Integrated luminosity measured in inverse femtobarn**

- Cross sections are measured in *barns* (with *one barn* being a very large cross section)

→ *Typical (interesting) cross sections at LHC are pico- and femto- barns*

→ *That's  $10^{-12}$  and  $10^{-15}$*

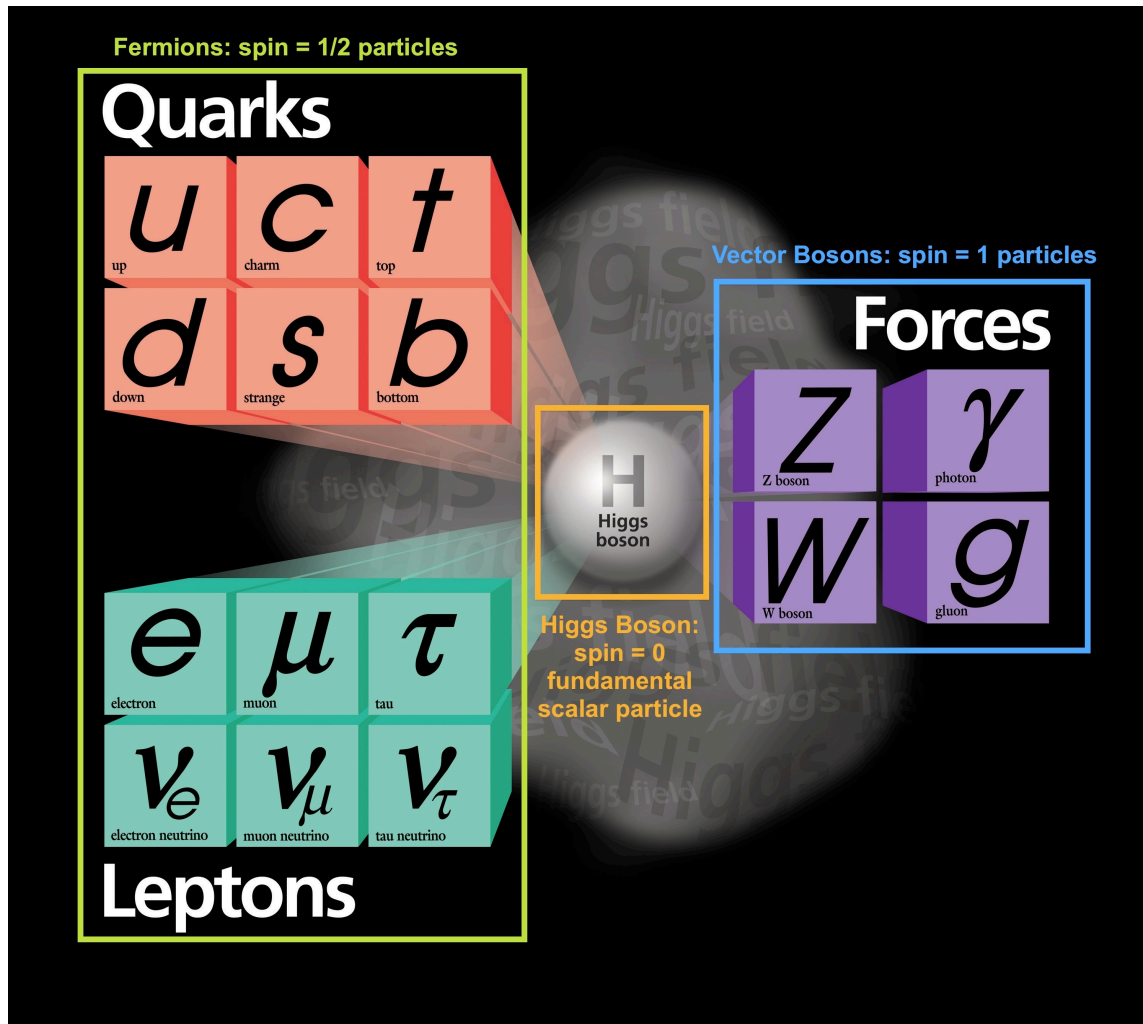

- Quantify “amount of data” by number of events for a process with a particular cross section

$$N = \left( \int \mathcal{L} dt \right) \sigma \text{ so } \int \mathcal{L} dt = N / \sigma$$

# The Standard Model: Theorist View

Fermions and bosons are building blocks, complexity is in interactions

# Hadron Collider Experimentalist's View

Every particle has a personality

**Spin = 1/2 particles**

These make jets

Heavy; distinctive decay to Wb

Good energy resolution

taggable jets!

**Spin = 1 particles**

Forces

Easy ID and measure

Not so easy

Higgs boson: spin = 0 fundamental scalar particle

Everywhere... so many gluons... (these make more jets)

The new kid, bit of a rock star

We like Ws and Zs: easy to identify experimentally

Monte Carlo with simulated detector

$\mathcal{L} = -\frac{1}{4} F_{\mu\nu} F^{\mu\nu} + i\bar{\psi}\not{D}\psi + h.c.$

Particles shown:  $u$  (up),  $c$  (charm),  $t$  (top),  $d$  (down),  $s$  (strange),  $b$  (bottom),  $e$  (electron),  $\mu$  (muon),  $\tau$  (tau),  $\nu_e$  (electron neutrino),  $\nu_\mu$  (muon neutrino),  $\nu_\tau$  (tau neutrino),  $H$  (Higgs boson),  $Z$  (Z boson),  $\gamma$  (photon),  $W$  (W boson),  $g$  (gluon).

# How we reconstruct particles

# Charged particle tracking

- Radiation conditions and occupancy (granularity) requirements  $\Rightarrow$  silicon semiconductor detectors closest to the interaction point:
  - $\rightarrow$  Strips: charge collection implants run the length of the detector
  - $\rightarrow$  Pixels: segmented in 2d detector plane, typical size  $100 \times 150 \mu\text{m}^2$  (current CMS)
- ATLAS (left): innermost layers silicon semiconductor (4 strip + 4 pixel), outer layers Transition Radiation Tracker (TRT): 4 mm straw tubes filled Xenon, pion/electron discrimination using x-ray photons from interstitial material

CMS (right): all silicon: 3-4 pixel layers and 8-14 strip layers

# Charged particle tracking

- Tracks bend in magnetic field produced by solenoid
- Helical trajectory defined by 5 track parameters
  - 2 impact parameters ( $d_0, z_0$ )
    - Critical to vertexing
    - Performance determined by pitch and radius of innermost tracker layers
  - 2 angles ( $\theta, \varphi$ )
  - curvature/momentum  $p$ 
    - Performance determined by “lever arm”: distance over which trajectory measured

# Charged particle tracking

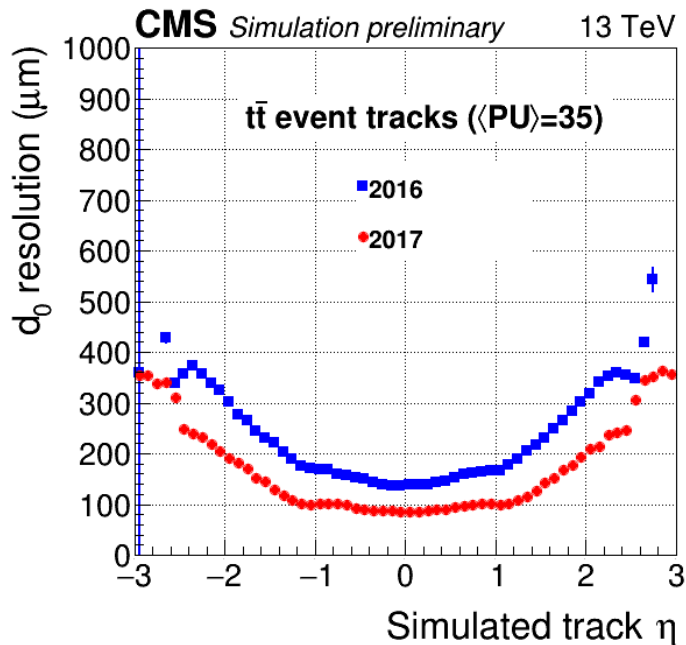

Adding a layer at smaller radius (**red points**) improves impact parameter resolution

→ *Multiple scattering affects tracks with  $p_T \lesssim 10$  GeV*

Conversely, momentum resolution gets better at lower momentum (to a point)

→ *Harder to measure curvature of straighter tracks*

**ATLAS added the IBL in 2014, CMS replaced their entire pixel detector in early 2017**

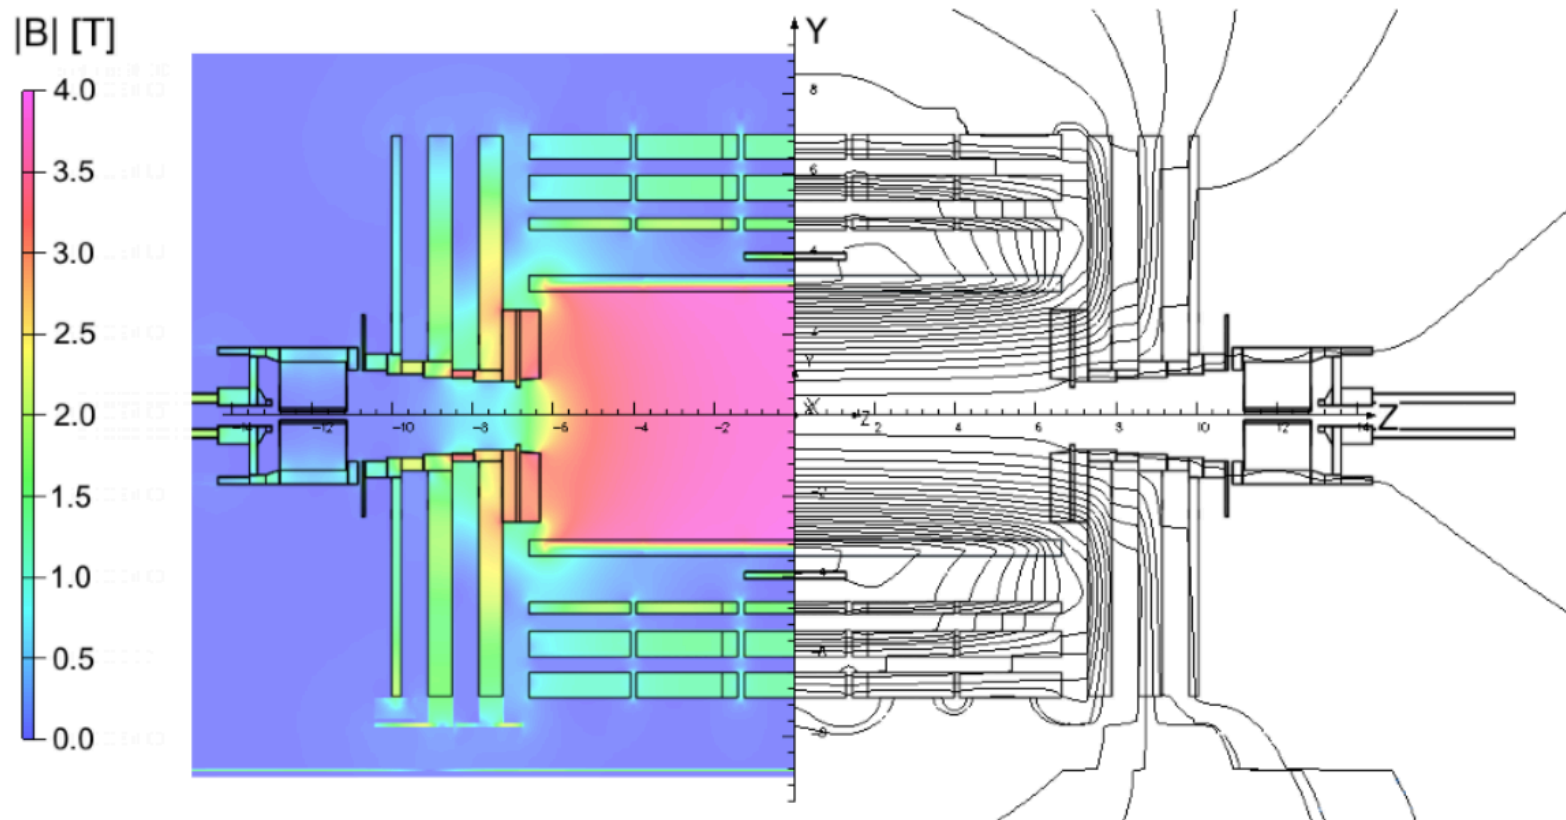

**CMS simulation from detector paper**

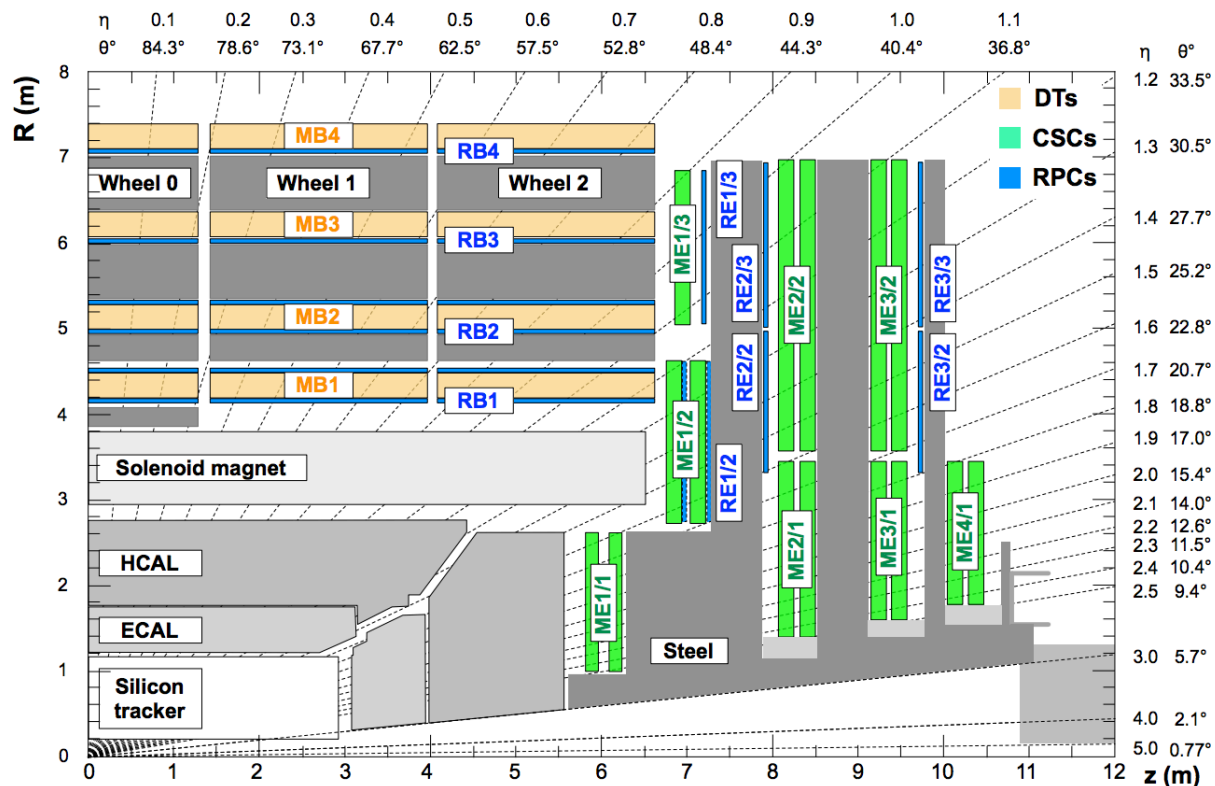

# Muons and magnetic fields

- Muons traverse the entire detector: ATLAS and CMS link tracks in two detectors, each with an independent momentum measurement
  - Solenoid: 2 Tesla, 2.4m diameter (ATLAS); 3.8 Tesla, 6m diameter (CMS)
  - ATLAS toroids produce magnetic field with field lines around the Z axis
  - CMS uses iron to direct flux return outside the solenoid, concentrating the field lines

# Muons and magnetic fields

- Muon detectors track charged particles using gas ionization
  - Lower rate and easier radiation environment but need to cover more area
- ATLAS, CMS work on similar principles; CMS described here (1306.6905)
- Drift tubes for precision: 200-300  $\mu\text{m}$  single-hit resolution ( $\sim 100 \mu\text{m}$  per station)
  - Position measured by time to drift to wire
- RPCs for speed
  - E field tuned to operate in “avalanche” mode
  - $\sim 1 \text{ cm}$  resolution
  - 3 ns time resolution and fast response (vs up to 400 ns for drift tubes; compare 25 ns collision spacing)
- CSCs split the difference
  - Tolerate higher event rates in forward region
  - 40-150  $\mu\text{m}$  resolution per station

# Muon performance

- Background rejection is a key feature of muons but harder to quantify: strong dependence on details of selection (number of hits, isolation, etc)

- Improved momentum resolution for highest- $p_T$  muons
- Efficient reconstruction  
 → *And well-understood: total uncertainty 1% or less*
- Calibrated using two-body decays

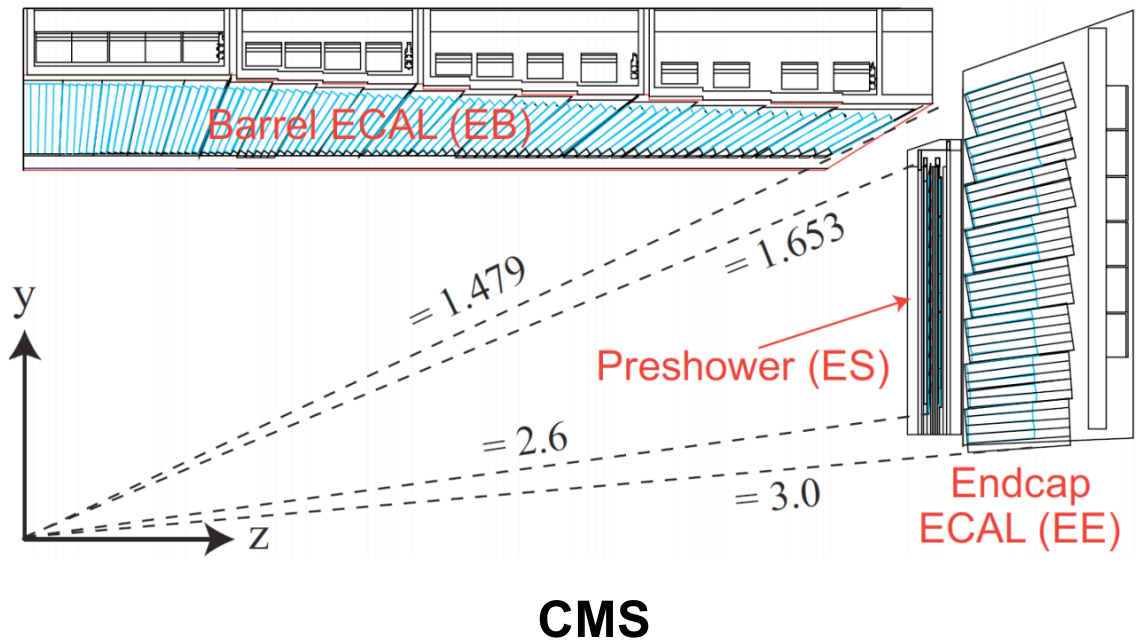

CMS 1804.04528

ATLAS PERF-2015-10

# Photons, electrons, and ECALs

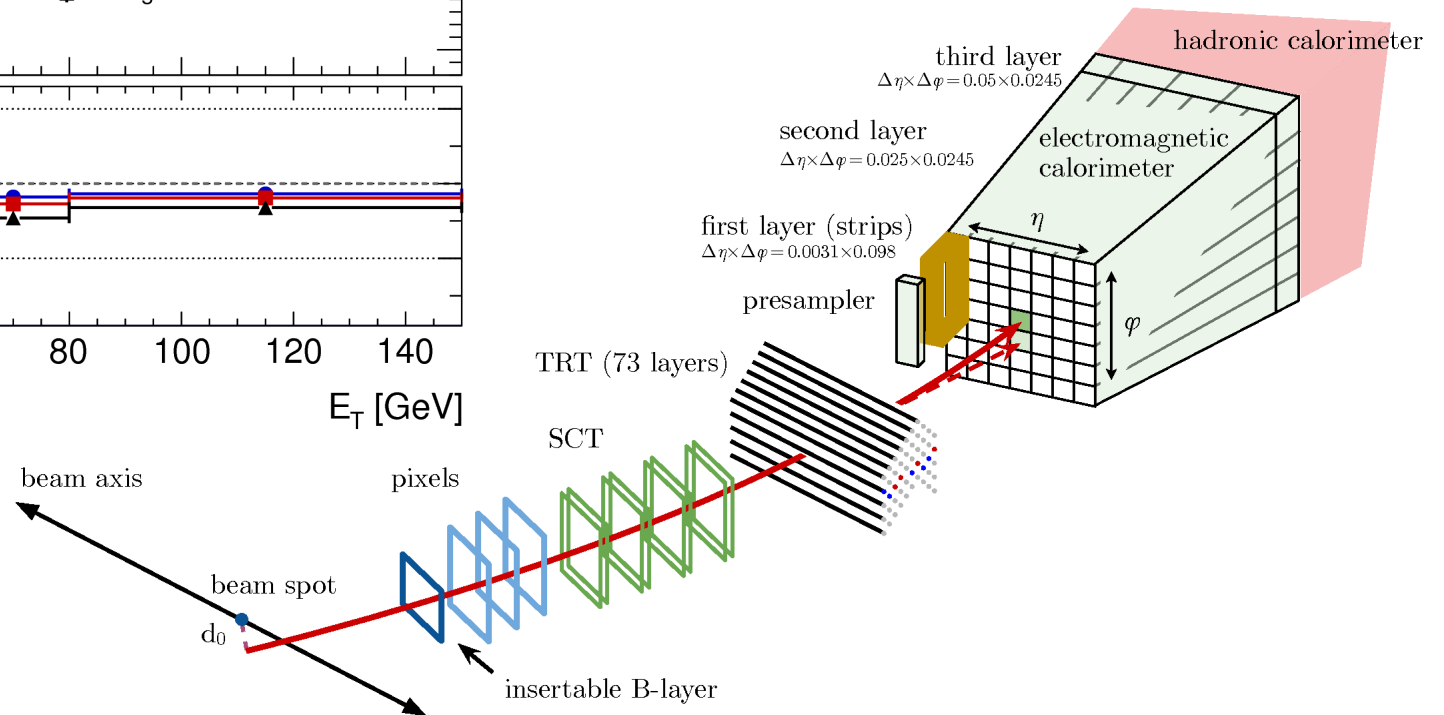

- Electromagnetic calorimeters from high-Z material (i.e. lead) to maximize electromagnetic interaction
- ATLAS and CMS made fundamentally different choices
  - ATLAS for background rejection ( $\pi \rightarrow \gamma\gamma$  in particular) using segmentation of electrodes; liquid argon for active material (ionization signal)
  - CMS for energy resolution: lead tungstate ( $PbWO_4$ ) crystals are dense (absorber) and produce scintillation light (active material)

# Electrons

- Combine tracks in inner detector with clustered energy deposits in electromagnetic calorimeter
- Tradeoff in background rejection and efficiency

# Photons

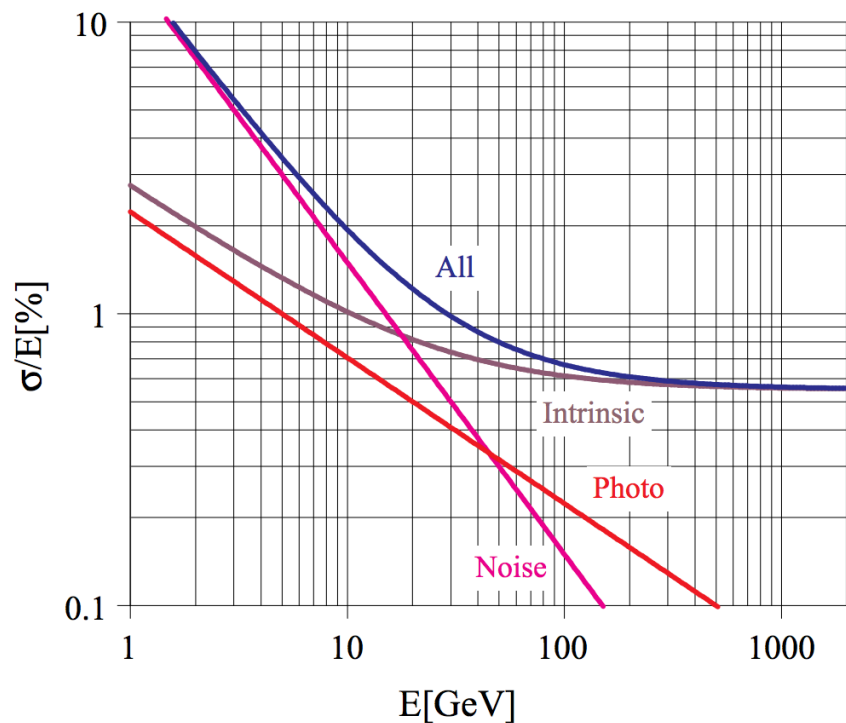

Reconstruct both converted and unconverted photons

→ *Converted have two tracks, particularly important for CMS, which has more material in the tracker:  $\geq 20\%$  of photons in  $H \rightarrow \gamma\gamma$  convert before reaching the calorimeter*

# Photons

- Energy scale (error on the mean): known to 0.1% -- 0.3% for energies relevant to  $H \rightarrow \gamma\gamma$
- Energy resolution (width of the distribution): around 1%

photon energy resolution (from CMS detector paper)

$$\left(\frac{\sigma}{E}\right)^2 = \left(\frac{2.8\%}{\sqrt{E}}\right)^2 + \left(\frac{0.12}{E}\right)^2 + (0.30\%)^2$$

**Stochastic** term  
“photo” : photon counting

**Noise** term:  
electronics + digitization

**Constant** term:  
nonuniform light collection,  
intercalibration errors, energy leakage from back of crystal

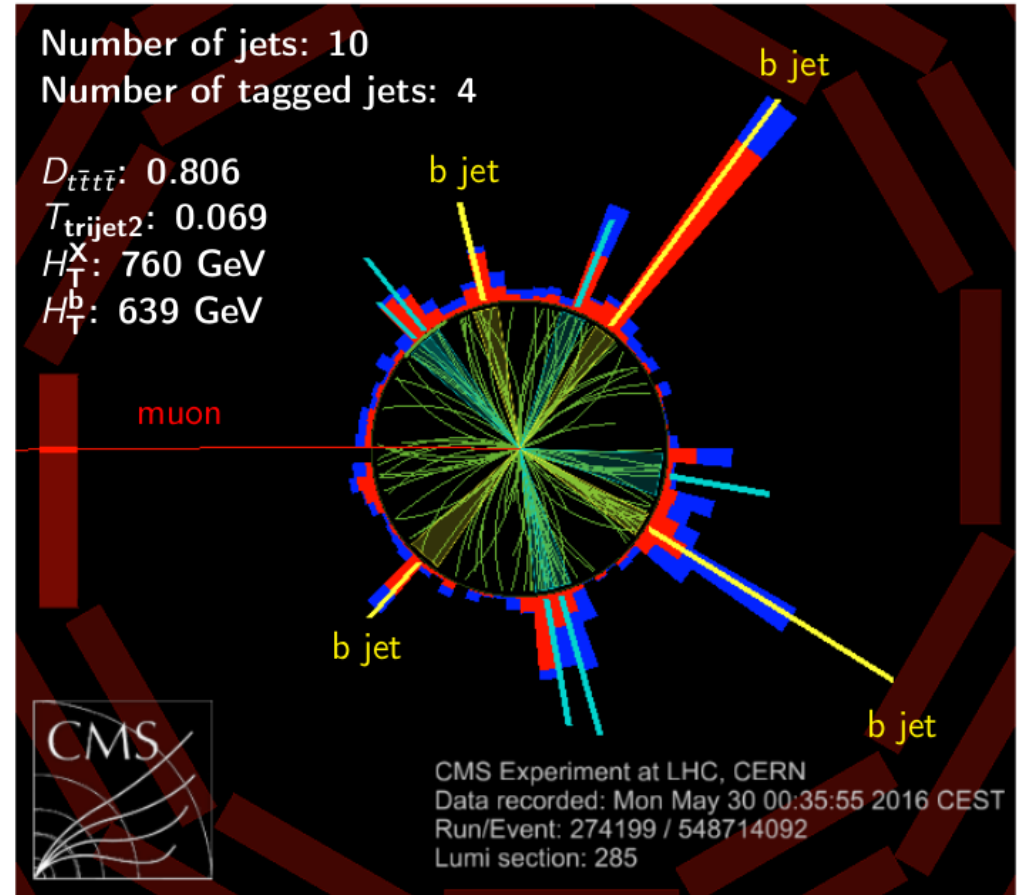

# HCAL and jets

- Hadron calorimeter designed to be as massive as possible to stop all particles, reconstruct hadron showers

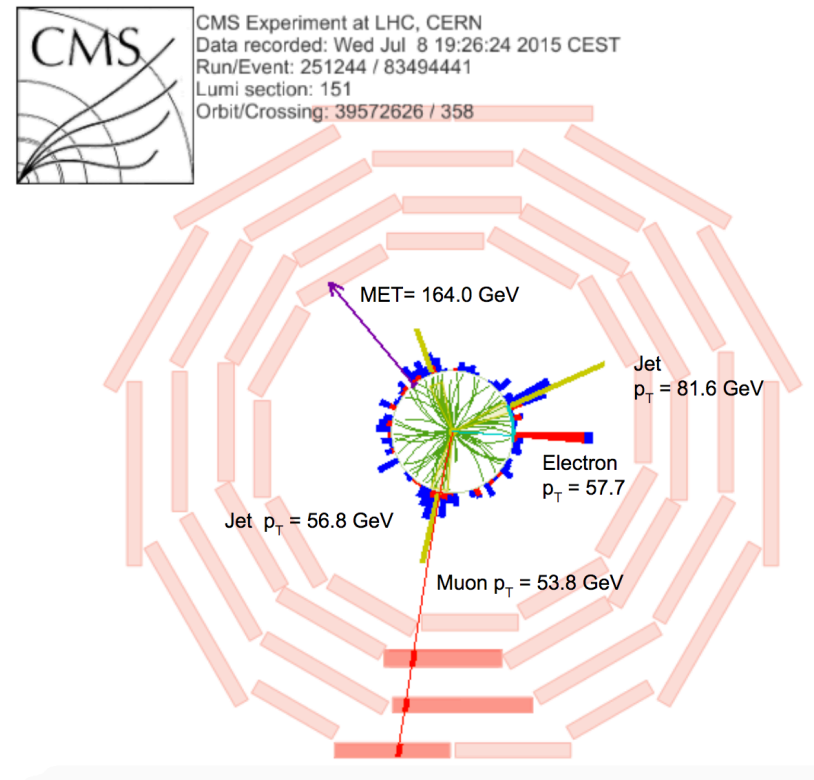

Reconstruct jets using **anti- $k_t$  algorithm**, but this reflects our intuition of localized energy deposit from fragmentation and hadronization of a high- $p_T$  quark or gluon

# Missing Transverse Momentum

Detect **neutrino** (or other weakly interacting neutral) by invoking conservation of momentum in the plane transverse to the beam

Resolution of unclustered part driven by stochastic effects: scales as  $\sqrt{\Sigma E_T}$

$$\vec{p}_T^{miss} = -1 \cdot \left[ \sum_{\text{jets } j} \vec{p}_T^j + \sum_{\text{leptons } \ell} \vec{p}_T^\ell + \sum_{\text{photons } \gamma} \vec{p}_T^\gamma + \sum_{\text{unclustered } u} \vec{p}_T^u \right]$$

# Building blocks: W and Z

At leading order,  
need an antiquark  
from the sea

# W Mass

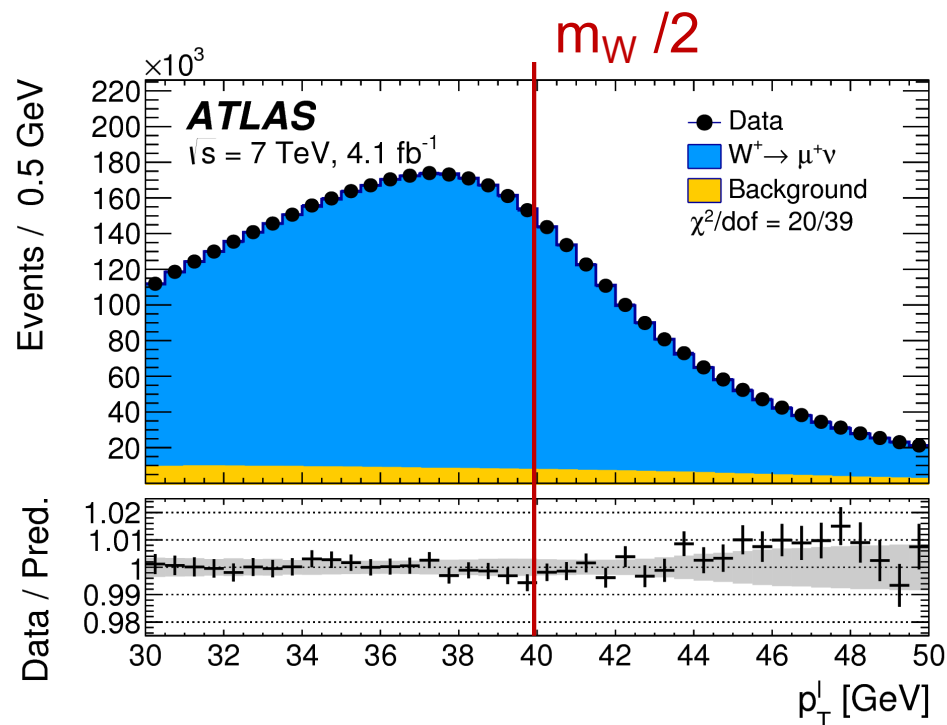

- ATLAS measurement with 7 TeV data (just under 5 fb<sup>-1</sup>)

→ *Not statistically limited*

- Fit to lepton p<sub>T</sub> and transverse mass  $m_T = \sqrt{2p_T^\ell p_T^{miss} (1 - \cos \Delta\phi)}$

→ *Kinematic edges at m<sub>W</sub>/2 and m<sub>W</sub>*

→ *Convolved with detector resolution,*

# W Mass

- Use Z events to model detector response, particularly recoil (unclustered energy)
  - *Similar production and kinematics*
- Sensitive to charm and strange quark content of the proton
  - *25% of W production involves 2<sup>nd</sup>-generation quark*

Channel	$m_{W^+} - m_{W^-}$ [MeV]	Stat. Unc.	Muon Unc.	Elec. Unc.	Recoil Unc.	Bckg. Unc.	QCD Unc.	EW Unc.	PDF Unc.	Total Unc.
$W \rightarrow e\nu$	-29.7	17.5	0.0	4.9	0.9	5.4	0.5	0.0	24.1	30.7
$W \rightarrow \mu\nu$	-28.6	16.3	11.7	0.0	1.1	5.0	0.4	0.0	26.0	33.2
Combined	-29.2	12.8	3.3	4.1	1.0	4.5	0.4	0.0	23.9	28.0

# W mass

$$\begin{aligned} m_W &= 80370 \pm 7 \text{ (stat.)} \pm 11 \text{ (exp. syst.)} \pm 14 \text{ (mod. syst.) MeV} \\ &= 80370 \pm 19 \text{ MeV,} \end{aligned}$$

- Fundamental test of internal consistency of Standard Model

# Weak mixing angle from DY $A_{\text{FB}}$

- Weak mixing angle is a free parameter of the SM

$$\sin^2 \theta_W = 1 - \frac{m_W^2}{m_Z^2}$$

- Measure **effective weak mixing angle** (includes EW corrections and is lepton-flavor dependent)

$$\sin^2 \theta_{\text{eff}}^f = \kappa_f \sin^2 \theta_W$$

- Theoretical expression for asymmetry:

$$A_{\text{FB}}^{\text{true}}(m_{\ell\ell}) = \frac{6a_\ell a_q (8v_\ell v_q - Q_q K D_m)}{16(v_\ell^2 + a_\ell^2)(v_q^2 + a_q^2) - 8v_\ell v_q Q_q K D_m + Q_q^2 K^2 (D_m^2 + \Gamma_Z^2 / m_Z^2)}$$

vector and axial couplings of fermions (leptons and quarks) to Z

$$v_f = a_f (1 - 4|Q_f| \sin^2 \theta_{\text{eff}}^f) \quad \text{where } Q_f \text{ is the fermion charge}$$

# Weak mixing angle from DY $A_{FB}$

- Ratios and asymmetries are powerful measurements because uncertainties on the total yield cancel to first order
- Define “forward” direction as  $\cos \theta^* > 0$ , where  $\theta^*$  is defined in the Collins-Soper frame

→ Parton  $p_T$  is small compared to other momenta so this is close to the lab frame

- Valence quarks, but antiquarks only from the sea → momentum asymmetry → quark direction more likely to be in the direction of dilepton system boost

→ Calculate  $\cos \theta^*$  under this assumption

→ Account for dilution

- Measured asymmetry defined

$$A_{FB} = \frac{\sigma_F - \sigma_B}{\sigma_F + \sigma_B}$$

This is a 2-d projection but that's all we need

# Weak mixing angle from DY $A_{FB}$

- Asymmetry largest for furthest-forward leptons, away from Z peak  
→ *But changes in  $\sin^2(\theta_{eff}^l)$  most evident near the Z peak*

- Sensitivity to PDF model also evident

# Weak mixing angle from DY $A_{FB}$

$$\sin^2 \theta_{\text{eff}}^{\ell} = 0.23101 \pm 0.00036 \text{ (stat)} \pm 0.00018 \text{ (syst)} \pm 0.00016 \text{ (theo)} \pm 0.00031 \text{ (PDF)}$$

- Limiting systematic is PDFs, statistical uncertainty from Monte Carlo
- Recall percent-level uncertainties on lepton ID: reduced to per-mil effect
- PDF replicas weighted by how well the model agrees with data

→ *Final result is a  $\chi^2$ -weighted average over the replicas, uncertainty is the weighted RMS*

→ *PDF uncertainty reduced by factor 2, still dominant*

# Cross section, simple view

- Cross section formula

$$\sigma = \frac{N - B}{A \varepsilon \int \mathcal{L} dt}$$

$N$  = number of events observed in selected data

$B$  = estimated background

$A$  = Acceptance

$\varepsilon$  = Efficiency

$\int \mathcal{L} dt$  = Integrated luminosity

Acceptance  $A$  purely from theory

$$A = \frac{N(\text{kinematic})}{N(\text{total})}$$

Fraction of total events that pass kinematic selection (fiducial volume)

Efficiency  $\varepsilon$  brings in detector effects (measure using simulated events and detector)

$$\varepsilon = \frac{N(\text{reconstructed})}{N(\text{kinematic})}$$

Fraction of events in fiducial volume that pass all event selection

# Cross section, simple view

- Cross section formula

$$\sigma = \frac{N - B}{A \varepsilon \mathcal{L}}$$

$N$  = number of events  
observed in selected data  
 $B$  = estimated background  
 $A$  = Acceptance  
 $\varepsilon$  = Efficiency  
 $\mathcal{L}$  = Integrated luminosity

- Uncertainties follow by error propagation with the statistical uncertainty  $\delta N = \sqrt{N}$

$$(\delta\sigma)^2 = \frac{N}{(A\varepsilon\mathcal{L})^2} + \underbrace{\left(\frac{\delta B}{A\varepsilon\mathcal{L}}\right)^2}_{\text{red}} + \underbrace{\left(\frac{\delta A}{A}\right)^2 \sigma^2 + \left(\frac{\delta\varepsilon}{\varepsilon}\right)^2 \sigma^2}_{\text{blue}}$$

**If the *absolute* uncertainty on your background is larger than your signal, no sensitivity (to see this, divide through by  $\sigma^2$ )**

**Fractional uncertainty on the acceptance and efficiency apply to the cross section**

# Cross section, modern view (I)

- Likelihood fit takes into account both the nominal expected signal and systematic uncertainties as nuisance parameters
  - We say that the nuisance parameters are “profiled”
- Models the probability to observe a certain number of events in a certain bin

$$\mathcal{L}(\mu, B(\boldsymbol{\theta})) \propto P(N_{obs} | \mu S(\boldsymbol{\theta}) + B(\boldsymbol{\theta})) \prod_i \exp\left(-\frac{(\theta_i - \theta_i^0)^2}{\sigma_i^2}\right)$$

**Poisson distribution describing the predicted and observed yield in each bin**

Expectation is sum of signal S and background(s) B

- Both a function of nuisance parameters  $\boldsymbol{\theta}$
- Signal strength  $\mu$  “floats” unconstrained

$$\mu = \sigma_{\text{measured}} / \sigma_{\text{predicted}}$$

(To extend to multiple bins, take a product of Poisson distributions)

**Product of gaussians, one per (uncorrelated) source of uncertainty**

- The  $\theta_i$  are allowed to vary in the fit, but we say that they are “constrained” by this gaussian
- $\theta_i^0$  is the nominal value of the uncertain parameter
- $\sigma_i$  is the uncertainty on parameter  $i$

# Cross section, modern view (II)

- Can fit for parameters other than cross section
- Equivalent to maximizing the likelihood: minimize negative log likelihood  
→ *Simplify computation*

$$-\log \mathcal{L} = -(\mu S(\boldsymbol{\theta}) + B(\boldsymbol{\theta})) + N_{obs} \log(\mu S(\boldsymbol{\theta}) + B(\boldsymbol{\theta})) + \sum_i \frac{(\theta_i - \theta_i^0)^2}{\sigma_i^2} + \text{constants}$$

- A typical likelihood scan
- Well-behaved: quadratic shape
- Central value at minimum
- Read 1- and 2-sigma uncertainty from points where  $-2 \log \mathcal{L}$  has increased by 1 and 4
